Letter to Readers

Our goal in writing *Fundamentals of HVACR* is to encourage a high level of professionalism for future and current technicians in the industry by producing a text that is both accessible and thorough. To accomplish this, we followed a few guiding principles:

- Explain why things work.
- Organize material so that it progresses from fundamental concepts to specific applications of those concepts.
- Organize the material so that it progresses in difficulty from easily understood ideas to more challenging concepts and applications.
- Write a text that is accessible to readers while still providing the detailed information necessary to be successful.
- Write a book that HVACR students will want to keep for reference when they become professionals.

The “HVACR Science” section lays the foundation for understanding virtually all the concepts and applications introduced later in the book. Taking the time to understand the science behind HVACR systems is an investment in your future. The specific details of individual units change over time, but the science that governs how they operate stays the same.

The most difficult part of writing a comprehensive text is deciding what material to include. Everything there is to know simply won’t fit into a single book. We focused on one simple question: Does the material help the reader understand how to install, maintain, and service HVACR systems?

The presentation of the material is equally important. There is always more than one way to describe or explain something. We chose the most transparent and easily understood explanations possible without leaving out crucial detail. Concepts and applications are reinforced with specific, real-world examples. Our writing style is engaging to draw the students in, as there is really no reason a textbook can’t be written in a style that encourages the reader to read out of interest rather than obligation.

HVACR students and technicians are our target audience. Most technicians are visually oriented learners. A good picture or illustration can often explain more than several pages of text, so we have included many pictures, illustrations, graphs, and diagrams to show everything from basic concepts to operational sequences.

One of the great things about teaching is sharing in other people’s success. There is nothing more gratifying than seeing students succeed. We hope that this book launches you on a successful HVACR career and finds a permanent place in your library or service truck.

Take the Guided Tour

PEARSON'S CURRICULUM SOLUTION FOR HVACR

We didn't just revise this textbook. We rethought the way you use it and the way you teach with it. We revised the entire line of materials for your HVACR program. Every item, from the supplements to the PowerPoints and the media program, was evaluated so that they would all seamlessly

cover your entire curriculum. We wanted to save you time and headaches while giving your students a consistent and engaging learning experience for their entire degree or certificate.

PEARSON CLASS MASTER

Your program requires a lot of material—textbook, videos, online media, PowerPoint slides, lecture notes, and more. You have to juggle and then customize them for your teaching. That is a lot of work. But *not anymore*.

With **Class Master** you just build your calendar, select your topics, and instantly you have your syllabus. Not just a syllabus—it tailors our lecture notes to your schedule.

What's more, you now know exactly what student and instructor tools are needed and available for each day.

Finally, **Class Master** will include a list of learning objectives in your instructor syllabus mapped to industry standards like AHRI's ICE and HVAC Excellence to assist you with accreditation and planning sessions.

MyHVACLab

With a **new and intuitive interface**, double the videos (over three hundred minutes), more simulations, eBook, grade book, and online study notes, **MyHVACLab** is back and unlike anything you've ever seen. With over **fifty new** gaming simulations added, service calls have never been this much fun.

Instructor Supplements

Comprehensive and broad in scope, we've left nothing to chance.

The supplements have been revised from the ground up, are integrated into **Class Master**, and are mapped to industry standards.

- Robust instructor's manual with new detailed lecture notes customized to your needs
- Expanded test questions for every learning objective in your program
- Additional labs in the print manual, plus more in MyHVACLab and the Pearson Custom Library
- The PowerPoint presentations have been completely revised from the ground up, making them more striking and matching them to all key objectives

Fundamentals of HVACR, 2nd Edition

Created with a clear-cut vision of what students need, this groundbreaking text provides comprehensive coverage of heating, ventilating, air conditioning, and refrigeration. This fully updated edition includes additional coverage of electrical, commercial, codes, and sustainability.

Learning Objectives

Each unit begins with clearly stated objectives that enable you to focus on what you should achieve by the end of the unit.

OBJECTIVES	
After completing this unit, you will be able to:	
1. define <i>refrigerant</i> .	5. describe the pressure-temperature relationship of saturated refrigerant.
2. identify the type of refrigerant by its number designation.	6. list the different types of refrigerant contaminants.
3. list the different types of refrigerant chemical composition.	7. explain the refrigerant safety rating system.
4. explain the difference between compounds, zeotropes, and azeotropes.	8. match refrigerants with the proper refrigeration oil.

Unit Introductions and Unit Summaries

These pull together the main points of the unit to prepare and remind students of what they should remember.

19.1 INTRODUCTION

Any study of the refrigeration cycle would be incomplete without a look at the refrigerant in the system. The refrigerant is the first component of a refrigeration system that must be determined, since its chemical and physical properties will play a large role in selecting all other components in a refrigeration system. A number of materials have physical and thermodynamic properties that make them suitable for use as refrigerants. In fact, anything that can boil at a low temperature and condense at

UNIT 19—SUMMARY

Refrigerant is the fluid used in a refrigeration system to transfer heat. It does this by absorbing heat while evaporating at a low pressure and temperature and condensing at a high pressure and temperature. Refrigerants may be classified by many characteristics, including the following:

Operating Pressure
Very high pressure
High pressure

Review Questions

Every unit has a set of review questions to help the reader assess his or her understanding of the material.

UNIT 19—REVIEW QUESTIONS

1. Define *refrigerant*.
2. What organization has established the number designation for refrigerants?
3. What are the chemical components of CFC refrigerant?
4. What are the chemical components of HCFC refrigerant?
5. What are the chemical components of HFC refrigerant?
6. What is ozone?
7. Which chemical family of refrigerants has the highest ozone-depletion potential?

Caution Tips and Safety Tips

These tips contain information students should know to operate equipment properly and protect themselves from harm.

CAUTION

Do not use pliers to tighten or loosen brass fittings. No matter how delicately you use pliers on these fittings, the fitting surface will be damaged. This damage can prevent the next technician from using the proper wrench on the damaged fitting.

SAFETY TIP

Some portable electric tools provide for double-insulated casings and do not need to be grounded. This type of tool may only have a two-prong plug rather than three. If a tool plug has three prongs, never use an adapter to make it fit a two-prong receptacle unless the adapter is properly grounded.

Code Tips

These tips help students provide additional information about codes that technicians will need to know.

CODE TIP

On December 7, 2009, the EPA declared that the current and projected atmospheric concentrations of the six key, well-mixed greenhouse gases, including HFCs, "threaten the public health and welfare of current and future generations." While no regulations are currently in place in the United States to regulate or phase out HFC refrigerants, the statement does establish the justification for future HFC regulations.

Tech Tips and Service Tips

These tips provide extra detail and information for students who want to go beyond the basics and get practical applications for the information in the unit.

TECH TIP

Air-conditioning and refrigeration hand tools do not get as dirty as most mechanics' tools will. However, it is a good idea to wipe them down with a clean, dry rag after each use. In addition, from time to time they should be rubbed with a lightly oiled cloth to protect them from rusting.

SERVICE TIP

Wrenches should always fit securely over the bolt head or nut before force is applied. If the wrench slips, you will jam your fingers. It is always best to try to pull rather than push on a wrench (Figure 4-39). You will have more control and will be less likely to jam your fingers or rap your knuckles. If you must push, then use an open palm so you're your fingers do not become jammed between the wrench and the work as the wrench begins to turn (Figure 4-40).

Green Tips

These tips provide important details about sustainable practices in the HVAC industry.

GREEN TIP

Blower door readings are useful when performing house tightening. They provide an objective measurement of the degree of improvement achieved.

COMPREHENSIVE TEACHING AND LEARNING PACKAGE

FOR THE INSTRUCTOR

To access supplementary materials, go online to www.pearsonhighered.com/irc and register. Within forty-eight hours you will receive a code via e-mail and instructions. Within forty-eight hours of registering, you will receive a confirming e-mail including an instructor access code. Once you have received your code, locate your text in the on-line catalog and click on the Instructor Resources button on the left side of the catalog product page. Select a supplement, and a login page will appear. Once you have logged in, you can access instructor material for all Prentice Hall textbooks. If you have any difficulties accessing the site or downloading a supplement, please contact Customer Service at <http://247pearsoned.custhelp.com/>. *Note:* The supplements are also housed in MyHVACLab at www.MyHVACLab.com.

Class Master

You can gain access to the Class Master Web site through the supplements pages referenced above and through MyHVACLab. Once you are at Class Master, you will not need a new password. There is a walk-through to guide you through the system.

Instructor's Manual with Lecture Notes and Correlation Guides ISBN-10: 0-13-287932-8

Even though you can customize your own instructor's manual through Class Master, you can also download a PDF of it as well. We've also created downloadable correlation guides to show you how our content matches other books and industry standards like AHRI's ICE and HVAC Excellence.

PowerPoint Slides ISBN-10: 0-13-288088-1

These comprehensive, colorful PowerPoint slides provide a powerful lecture or study tool.

Lab Manual ISBN-10: 0-13-287974-3

The print lab manual covers the basics, providing you and your students with labs for every key topic in the book. There are approximately three hundred labs in the print version, and four hundred more are waiting for you at

www.pearsoncustomlibrary.com, where you can choose all the labs you want for your courses. You can build a lab manual for every course to your specifications, choosing from all of our HVACR labs. It will give you a custom ISBN, and your bookstore can order it just like it would a traditional book.

MyTest ISBN-10: 0-13-286113-5

MyTest is a comprehensive set of test questions matching key objectives for all of your courses.

FOR THE STUDENT AND INSTRUCTOR

With a **new and intuitive interface**, **MyHVACLab** provides learning management tools to save you time as well as media and assessment to engage and track your students. With over fifty new service-call simulations, and more than three hundred minutes of video, your students will have a learning experience like none other. Each unit includes

- Objectives and outlines
- eBook
- Homework questions
- PowerPoint slides
- Digital flashcards
- Animations of key concepts
- Interactive exercises
- Concept spotlights: multimedia cliff notes for the book
- Video clips

- A pretest and a posttest
 - This supercharged study guide allows students to take a pretest to determine what they don't already know. It will then create a customized study plan based on those learning needs. A posttest follows to make sure they have learned everything they need to know.

AHRI and HVAC Excellence Correlation Guides

Standards for these two associations have been mapped to our materials.

About the Authors

Carter Stanfield is program director of the Air Conditioning Technology Department at Athens Technical College, where he has taught since 1976. His industry credentials include both an RSES CM and NATE certification and a State of Georgia Unrestricted Conditioned Air Contracting license. He graduated from the University of Georgia magna cum laude in 1995 with a bachelor of science degree in education. Mr. Stanfield believes that successful educational programs are focused on what the students do. Students start with a strong background in fundamental concepts and theory and then actively apply them to solve real problems. Practice and active application are the keys to students building both confidence and competence. For teaching tips and more, see his HVACR blog at <http://hvacrfundamentals.blogspot.com/>.

David Skaves, P.E., has been a faculty member at the Maine Maritime Academy since 1986 and received the Teaching Excellence award at the college in 2006. His career background includes employment as a marine engineer on supertankers in the merchant marine, a production planner at Maine's Bath Iron Works Shipbuilding, and an

engineering consultant for combined cycle power plant performance testing throughout the United States as well as in Mexico and South America. In addition to his MBA from the University of Maine at Orono, Professor Skaves is a registered professional engineer, licensed first-class stationary engineer, and licensed marine chief engineer. He is currently a member of ASHRAE, AFE, and the Maine State Board of Boiler and Pressure Vessels.

Freddie Williams is the author of **MyHVACLab** and the program chair of the Air Conditioning Technology Department at Lanier Technical College, with over twenty-three years of professional experience. Mr. Williams is a graduate of Athens Technical College and has been a faculty member at Lanier Tech since 2002, teaching air conditioning and industrial systems. He was awarded Instructor of the Year at Lanier Tech in 2010 and the Master Teacher award in Hall County, Georgia, in 2010. Mr. Williams is a member of ASHRAE and RSES and holds degrees in management and technical studies. He has extensive experience with electrical and mechanical systems in industrial, commercial, and military environments.

UNIT 1

Introduction to Heating, Ventilation, Air Conditioning, and Refrigeration

OBJECTIVES

After completing this unit, you will be able to:

1. give a brief history of HVACR.
2. define environmental heating and air conditioning.
3. give the advantages of freezing foods quickly.
4. explain the importance of having a clean background.
5. list the various types of HVACR jobs and explain what they might do.
6. list the HVACR professional organizations.

1.1 INTRODUCTION

The abbreviation HVACR is certainly a mouthful, and so it is not unusual to ask the question, “What does this mean, and how does it impact me?” However, the answer is not so simple, and a standard definition may not explain very much. This is because the HVACR industry is a complex network that our entire society relies on more today than ever before. Just think how your world would change without refrigeration for your food or drinks and without air conditioning in your car or classroom. Try to visualize how this would affect the greater population, from food distribution networks, to hospital care, to housing for the elderly. As a trained and skilled HVACR technician, you can make a positive impact on society. You can contribute to this growing industry to ensure that systems work efficiently and safely and are environmentally friendly (Figure 1-1).

Figure 1-1 Think green! New innovative technologies will allow some HVACR systems to operate on power supplied by wind turbines.

1.2 HISTORY AND OVERVIEW OF HVACR

Heating

In an attempt to better understand HVACR, let's break it down component by component. The *H* for *heating* seems easy. The history of heating a space by burning wood starts in our earliest times and continues to the present. Elaborate systems using firewood heated Roman buildings. Channels were built underneath the floors to draw heat from a fire, thus warming the building and creating the first central heating systems (Figure 1-2).

Wood, peat, and coal remained the primary heating fuels for centuries. Many early buildings had open fireplaces. But fireplaces are an inefficient way of heating because too much of the heat produced is drawn up the chimney. Although early seventeenth-century European masonry-type stoves burned wood safely at high efficiency, the next

Figure 1-2 Romans used fires channeled below floors as early heating systems.

Figure 1-3 Woodstove.

major step in heating technology in America was the metal stove. Benjamin Franklin is credited with inventing a cast-iron stove that was several times more efficient than any other stove at that time. Many people still use decorative, efficient stoves to provide much, if not all, of their heating needs (Figure 1-3).

However, wood heat is only one alternative, because today there are many more choices for heating. Gas heat, oil heat, electric heat, and solar heating systems are common. Heat pumps that use a refrigeration system for heating can be very efficient. Geothermal heating systems that utilize the heat from within the earth are becoming more popular. New, environmentally friendly ideas and efficient designs are continually being developed, tested, operated, and maintained by people just like you entering the industry. So you can see that just the *H* alone is a large and important sector.

Ventilation

Next comes the *V* for *ventilation*. Before the invention of chimneys, fires were burned in the center of a room with smoke having to escape through holes in the roof. When early homes were heated by wood fires, the smoke would permeate the entire building. Although people were warm, the health hazards from this smoke exposure were harmful. As an improvement, early Norman fireplaces in England were designed to allow the smoke to escape through two holes in the side of the building. It was obvious that something needed to be done to improve the air quality.

A properly ventilated building allows for the air to flow and exchange so that harmful particulates such as those in smoke are not allowed to accumulate. Fresh air also brings oxygen into the space, but it becomes depleted over time. A simple ventilation system can consist of only a fan and some minor ductwork for transporting the air. More complex systems circulate air throughout entire buildings through a vast network of ducts and blowers.

Figure 1-4 When water evaporates, heat is absorbed. This change of state is also referred to as a phase change.

Air Conditioning

The AC stands for *air conditioning*. Generally this is considered by most people to be a way to cool a space, but as you will learn, this term encompasses much more. Artificially cooling the air in a living space dates back to the earliest centuries. In ancient Greece, large wet woven tapestries were hung in natural drafts so that the air flowing through and around the tapestries was cooled by the evaporating water. As the water evaporated it would remove heat, just like when you perspire to remain cool (Figure 1-4). Some manufacturers sprayed water in factories for cooling as early as the 1720s. Evaporative cooling is still used extensively in residences and businesses throughout the southwestern United States, where typical summer conditions are very hot and dry.

Ice was the primary means of cooling air for many years. The Romans packed ice and snow between double walls in the emperor's palaces. John Gorrie patented the first mechanical air-conditioning system in 1844. His system was used to cool sick rooms in hospitals in Florida. The United States capitol building in Washington, DC, was first air conditioned using ice in 1909. Rumor has it that when the legislators got really involved in controversial debates, more ice was required to keep the building cool. The phrase "tons of air conditioning" we use today came from this era in history, when tons of ice were used for cooling (Figure 1-5).

Figure 1-5 When ice melts, heat is absorbed.

TECH TIP

Refrigerant capacity is measured in tons. One ton of capacity is equivalent to the amount of heat that 2,000 lb of ice can absorb in one day. The amount of latent heat required to change 1 ton of ice into 1 ton of water is 288,000 BTU. If this amount is divided by 24 hr per day, the equivalent is 12,000 BTU/hr.

Refrigeration

Finally, the *R* stands for *refrigeration*, which is a necessary component for most air-conditioning systems; however, refrigeration systems are more commonly considered to be used for keeping food cold. That is why very often you may see the abbreviation HVAC, which implies air conditioning only. The broader term HVACR includes both air conditioning and refrigeration systems.

The first use of refrigeration was for the preservation of food. Ice was harvested from frozen lakes and stored for later use. Sometimes it could be kept all summer long in ice houses. Ice harvesting remained a flourishing industry well into the twentieth century.

Archeologists have discovered that the first evidence of man making ice appeared more than 3,000 years ago, about 1,000 BC. Peoples living in northern Egypt, the Middle East, Pakistan, and India made ice using evaporation. Archeological excavations in these regions have discovered ice-producing fields that covered several acres. The ice was produced in shallow clay plates, about the size of a saucer. The water in these clay plates wept through the clay. This water dampened the small straw mats holding the clay plates in racks a few feet above the ground (Figure 1-6). The straw aided evaporative cooling of the water. Under the right conditions of temperature and humidity, a thin film of ice would form overnight on each clay plate.

Producing ice in this way is also the principle behind modern snow-making equipment. A snow-producing machine like the one in Figure 1-7 can make snow by evaporative

Figure 1-6 Ice was first artificially produced to be used for food preservation more than 3,000 years ago.

Figure 1-7 Snowblowers can produce artificial snow by evaporative cooling. (Courtesy of Red River Ski Area)

cooling even when the temperatures on the ski slopes are above freezing.

Today, a majority of refrigeration systems use what is referred to as mechanical vapor compression. The mechanical process of compressing a gas to produce cooling can be traced back to coal mines in England. Large steam-driven or water-powered compressors were used to force air into the deepest mines so miners could work in a safe atmosphere. Over long hours of operation, miners observed the formation of ice around the air nozzles (Figure 1-8). This ice was collected and used for food preservation. The construction of steam-powered compressed-air plants that produced ice soon followed. The first maritime refrigeration units were made by putting steam-powered compressors on sailing ships to make it possible for beef to be shipped from Australia to England, starting in 1876.

HVACR and the Refrigeration Cycle Now that you have a better understanding of what HVACR means, it is easy to see that it encompasses a broad spectrum of needs and applications. Although the methods for heating can vary considerably, the majority of cooling applications are based on the refrigeration cycle. When ice changes to water, heat

Figure 1-8 Ice forming around an air nozzle.

Figure 1-9 Water evaporates to vapor and absorbs heat, and then the vapor is condensed back to water to release its heat.

is absorbed, which makes ice a viable refrigerant. But ice is hard to store and takes up a lot of space. Water is easier to use because it can be pumped and doesn't need the insulation that ice requires. When water evaporates to vapor it also absorbs heat, but then the water needs to be replaced, and this uses up a lot of water over time.

If the vapor can be recovered and turned back into water, then this cycle reduces the total amount of water needed (Figure 1-9). Even so, the major disadvantage with this type of evaporative cooling is that the lowest temperature that can be reached is dependent on the properties of water.

Notice that with both ice and water, it is their change of state that allows for heat to be absorbed. It is this important principle that serves as the basis for most refrigeration

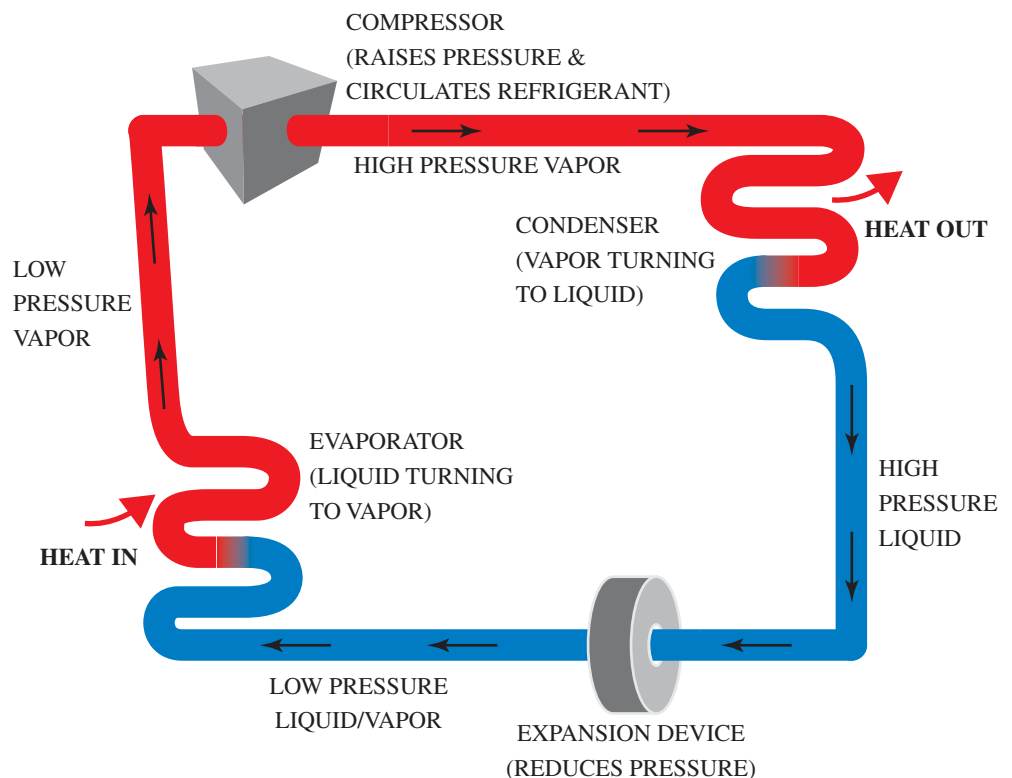

systems today, but instead of using water, other fluids with different properties and lower boiling points, called refrigerants, are now used. This allows for much colder temperatures, far below freezing. The "refrigeration cycle" therefore continually evaporates and condenses refrigerants to absorb and then throw away the heat.

A compressor is used like a pump to raise the pressure and circulate the refrigerant through the system (Figure 1-10). A condenser is used to remove heat from the refrigerant as it turns into a liquid. An expansion device drops the pressure to allow the refrigerant to change back from liquid to vapor in the evaporator. Heat is absorbed in the evaporator and then thrown away in the condenser. The refrigerant does not wear out and circulates around and around during operation. Most refrigeration systems in use today operate using this type of cycle.

1.3 TODAY'S HEATING, AIR CONDITIONING, AND REFRIGERATION

"Environmental heating and air conditioning" refers to the control of a space's air temperature, humidity, circulation, cleanliness, and freshness, and it is used to promote the comfort, health, and/or productivity of the inhabitants. Homes, offices, schools, colleges, factories, sporting arenas, hotels, cars, trucks, and other vehicles such as aircraft and spacecraft are heated and cooled. The main purpose of environmental heating or cooling is to help maintain the body temperature within its normal range. Generally, the term *air conditioning* is used when the space temperature is above 60°F (15°C), and *refrigeration* is the term used when the space temperature is below 60°F (15°C).

Figure 1-10 The basic refrigeration cycle consists of four major components: compressor, condenser, expansion device, and evaporator.

TECH TIP

Without our ability to control the environment, it would be impossible for us to explore space or the bottom of the ocean or even to enjoy the comfort of a transcontinental jet ride at 35,000 ft. So our ability to control our environment has served both to improve the quality of life and to enhance our scientific endeavors.

Process heating and cooling are used to aid in manufacturing or to keep equipment at a desired temperature. An area used to process meat or vegetables may be cooled to help preserve the product. Computer rooms are cooled so the equipment lasts longer and is able to stay online due to the heat being removed from the space. Computers would not operate properly if heat was not absorbed from the space. Remote pumping stations may be heated to prevent pipes from freezing. The main purpose of process heating or cooling is to maintain the temperature of things or processes within their required range.

TECH TIP

An operating room is cooled to aid with the surgery as well as for the comfort of the patient or surgeon. Therefore, an operating room is an example of process cooling even though it may be within the normal air-conditioning temperature range.

Modern Heating

Central heating of homes and businesses dates back to ancient times, but the first commercial warm-air fan-driven system was marketed in the 1860s. By the 1900s a number of different central warm-air systems were available for residential and commercial applications, and in 1908, the essential elements for heating, cooling, humidifying, dehumidifying, and filtering air were defined.

Today central heating systems can use warm air, hot water, steam, electric resistance, or a reverse refrigeration cycle (heat pump). The basic theory for the heat pump dates back to 1852.

Modern Air Conditioning

The development of modern air conditioning is often credited to Dr. Willis Carrier. Dr. Carrier, an engineer, was confronted with a problem facing printers. As paper was printed with one color, the dampness in the ink caused the paper to stretch slightly, and it was nearly impossible for the second color to be printed without being misaligned. Dr. Carrier determined that a means for controlling the humidity was necessary and developed the first air-conditioning system for the printing industry. His invention, called an "Apparatus for Treating Air," was patented in 1906 (Figure 1-11). His invention quickly found favor not only for dehumidifying but

Figure 1-11 The patent for the first apparatus for cooling air, invented by Willis Carrier.

also for cooling. Through the 1940s and 1950s, businesses would proudly display signs reading "Air Conditioned." Dr. Carrier designed the psychrometric chart as we know it today. (This chart displays the properties of air, such as temperature, humidity, and volume, and is commonly used for many HVAC applications.)

Mass air conditioning of homes began in the late 1950s with window air conditioners. Central residential air conditioning started to become popular in the mid-1960s. Today most of us cannot imagine living in a home anywhere in the country that does not have air conditioning.

Modern Refrigeration

Clarence Birdseye made another major contribution to the industry. He developed the process of freezing foods in 1922. Today, supermarket freezer displays provide us with a variety of food products that would not be possible to preserve any other way (Figure 1-12). In 2006, a new era in eating occurred when the American public purchased more heat-to-eat and thaw-to-eat foods than any other type of food.

Figure 1-12 Modern refrigeration display cases provide us with a variety of food products that would not be available without refrigeration.

- **Frozen foods** Before Clarence Birdseye began commercially freezing food, people had allowed food to freeze naturally during the winter months as a way of preserving it for later use. Food frozen this way did not always taste that good, so the trick was to come up with a way of freezing food and having it still taste good when it was thawed.
- **Quick freezing** The process of rapidly freezing food using air blast, contact, and/or immersion freezing was the key to improving the quality and taste of thawed frozen foods. The problem with freezing food slowly is that when ice crystals form over time, they become much larger. These large, sharp ice crystals grow through the cell walls of the food, and when the food thaws, all of the nutrients in the food are allowed to drain away. Quick freezing causes the ice crystals to be very small and less likely to penetrate cell walls, so the food retains nutrients and flavor when it is thawed.

1.4 EMPLOYMENT OPPORTUNITIES

The HVACR industry represents one of the largest employment occupations in the country. Our industry, for example, is one of the largest consumers of electric and gas utilities in the nation. More electricity and natural gas is consumed producing heating and cooling than for any other single use. The size of the industry has been growing steadily since the late 1960s, when residential central systems became popular. The installation and servicing of HVACR systems will always be an expanding occupation. No one builds a home or business without some type of heating and/or cooling system, which requires designing, installing, and servicing by skilled and trained technicians.

Residential Air Conditioning and Heating

Most residential heating systems have a heating capacity of 50,000 to 150,000 BTU/hr. The majority of residential air-conditioning systems are 5 tons or less. Both of these sizes

will obviously vary greatly, depending on the region of the country you are working in. In addition, there are many very large homes being built, requiring systems that could easily be classified as light commercial because of their size and/or complexity.

TECH TIP

To protect the public from potentially dangerous individuals, some businesses and/or local and state governments require criminal background checks on anyone involved with in-home service work. These checks may go back 25 years or more into an individual's past. Check with your local or state governmental department that regulates in-home service work if you feel there is something in your past that might affect your ability to work in residential service. In most states these checks are only required for in-home service work, so you may still be able to work in new construction or in the commercial or industrial areas.

Commercial Air Conditioning and Heating

The term *commercial* is used to refer to any system that is used in commercial buildings (for business) that provides cooling or heating. These systems may be as small as a fraction of a ton in size to several thousand tons in cooling capacity and/or from 1,000 BTU/hr to hundreds of thousands of BTU/hr.

Commercial systems may be operated independently of any other system or be integrated with a building automation system. Because of the vast differences in the types of equipment and system complexity, commercial technicians often specialize in a single type of system or group of systems.

Commercial and Industrial Refrigeration

The terms *commercial refrigeration* and *industrial refrigeration* are applied to retail food and cold-storage equipment and facilities. Examples of commercial equipment and systems include refrigeration equipment found in supermarkets, convenience stores, restaurants, and other food service establishments. Industrial refrigeration can include long-term storage either as cold storage or medium or low-temperature refrigeration systems that are generally larger-scale operations.

Types of Jobs

There are a variety of occupational specialties offered within the HVACR industry. These occupations range from the basic entry-level helper to the systems designer. Although the work involved with heating, air conditioning, or refrigeration equipment and systems is similar in theory, there is a significant difference between the work done in the areas of residential, light commercial, commercial, and industrial. These areas of heating, air conditioning, and refrigeration generally relate to the size (capacity) and complexity of the system. However, technicians may find the exact same equipment used in one home being used in a commercial shop or factory. In these cases the distinguishing factor is whether you are working in someone's home or in a business.

- **Entry-level helper** The entry-level helper (first-year apprentice) provides the senior technician with assistance installing and servicing equipment. Most medium and large mechanical contracting companies use a number of helpers to assist with the installation and service of residential and commercial systems. A helper may be expected to assist in lifting, carrying, or placing equipment or components. He or she may also run errands to pick up parts and clean up the area following installation or service. Helpers receive basic safety training, and if they will be driving, they must have good driving records.
- **Rough-in installer** The initial installation process is referred to as rough-in. In this process the technician (first- through third-year apprentice) will install the refrigerant lines, electrical lines, thermostat and control lines, duct boots, and duct run and set the indoor and outdoor units. The rough-in technician must have an understanding of duct layout, blueprint reading, and basic hand tools and good brazing skills.
- **Start-up technician** Once the system has been installed and all of the components are ready for operation, a start-up technician (fourth- and fifth-year apprentice) will go through the manufacturer's recommended procedures to initially start a system. Because much of the HVAC system has been field installed, this checkout procedure is essential to ensure safe and efficient operation. The start-up technician records all of the information requested by the manufacturer's warranty. Start-up technicians must be skilled with electrical troubleshooting and refrigerant charging and have good reading comprehension and writing skills.
- **Service technician** The service technician (fourth-year apprentice to journeyman) is the individual who provides the system owner with repair and maintenance. Service technicians are the people who must be able to diagnose system problems and make the necessary repairs. Service technicians must be skilled in diagnosing electrical problems, refrigerant problems, and air-distribution problems.
- **Equipment operator** Equipment operators are required by local ordinance and state law to be present anytime large central heating and air-conditioning plants are in operation. Their primary responsibility is to ensure the safe and efficient operation of these large systems. They must have a good working knowledge of the system's mechanical, electrical, and computer control systems to carry out their job. They sometimes need to hold a city or state license to become an operator. Equipment operators generally work by themselves or as part of a small crew. They often are required to have good computer skills when buildings have computerized building-management systems.
- **Facilities maintenance personnel** Facilities-maintenance personnel are responsible for planned maintenance and routine service on systems. They may work at a single location or have responsibilities for multiple locations, such as school systems. Facilities-maintenance personnel typically maintain systems and provide planned maintenance. They may work alone or as part of a crew, depending on the size of the facility. Maintenance personnel may from time to time have duties and responsibilities outside of the HVACR trades, such as doing minor electrical plumbing and carpentry projects for the upkeep of the building.
- **Service manager** A service manager is typically a skilled HVACR technician with several years of experience. This individual oversees the operation of a company or maintenance department. He or she must have good management skills, communication skills, and technical expertise. Service managers typically assign jobs to other technicians and employees. They must then oversee these individuals' jobs.
- **Systems designer** For small buildings, contractors normally size and select HVAC systems and equipment. There are many industry-standard sizing and design guides available from trade associations such as the ACCA (Air Conditioning Contractors of America). For larger buildings, mechanical, architectural, or building services engineers may be required by law to design and specify the HVAC systems. Specialty mechanical contractors will work with the design plans to build and commission these systems.

TECH TIP

Technology has enabled the field tech to stay in close contact with his service manager. This allows the highly experienced service managers to provide assistance to technicians as they come upon new problems. The technician can also call upon the office to research unique problems to determine the best, most efficient way of making the repair.

- **Sales** HVACR sales are divided into two major categories: inside sales and outside sales. Inside sales deal primarily with system sales to other air-conditioning contractors. Outside sales may be to both contractors and end users. Working in outside sales or consumer sales requires the technician to have a good understanding of cost and value of equipment so that the owner can make an informed choice.

1.5 TRADE ASSOCIATIONS

With the rapid growth and variety of interests, trade associations naturally evolved to represent specific groups. The list includes manufacturers, wholesalers, contractors, sheet metal workers, and service organizations. Each is important and makes a valuable contribution to the field. Space does not permit a detailed examination of all of these organizations, or all of their activities, but throughout the book many of these associations will be acknowledged as specific subjects are covered.

Certifications

Many trade associations offer training programs and competency examinations for the industry to help ensure a workforce of qualified technicians. In addition, the 1990 Clean

Air Act passed by the United States Congress requires that anyone who performs maintenance, service, repair, or disposal that could be reasonably expected to release refrigerants must be certified. To become certified, technicians are required to pass an Environmental Protection Agency (EPA)-approved test given by an EPA-approved certifying organization. Four different types of certifications have been developed to address different types of equipment. A person meeting the requirements for all four types is issued a universal certification. This is certification process is further described in Unit 28, Refrigerant Management.

Air-Conditioning, Heating, and Refrigeration Institute (AHRI)

The Air-Conditioning, Heating, and Refrigeration Institute (AHRI) is a national trade association representing manufacturers of over 90 percent of U.S.-produced central air-conditioning, gas appliances, and commercial refrigeration equipment. AHRI was formed in 2007/2008 when ARI (Air Conditioning and Refrigeration Institute) merged with GAMA (Gas Appliance Manufacturers Association). ARI, now AHRI, was originally formed in 1954 through a merger of two related trade associations and traces its history back to 1903 when it started as the Ice Machine Builders Association of the United States. Today AHRI has over 180 companies as members.

Many services are provided by AHRI to assist HVACR technicians. Some of these services, which would supplement this text, are listed below:

- ICE is an industry competency exam. This test is made available to students of educational institutions to test their knowledge of fundamental and basic skills necessary for entry-level HVACR technician positions. The information in this text covers the topics in the AHRI curriculum guide and would assist the student in taking this examination. A directory of those who pass the examination is published nationally to assist prospective employers in identifying job candidates.
- Equipment donations to schools participating in the ICE competency exam. AHRI contacts industry sources having no-cost or low-cost equipment available to supply a school's laboratory needs.
- Technician certification program. In accordance with EPA's enforcement of the Clean Air Act, the sale of refrigerants is made only to those technicians who have been certified. AHRI is among the many approved by EPA to administer the test for certification. In addition, AHRI provides study material to prepare for the test.
- Reclaimer certification program. EPA also requires certification of any processor of recovered refrigerant for resale. AHRI is among those assigned by EPA to carry out a certification program for companies that seek to reclaim refrigerants. Technicians handling reclaimed refrigerant should become familiar with the *Directory of Certified Reclaimed Refrigerants*, published every March and September by AHRI.
- Certification program for equipment used to recover and recycle refrigerant. AHRI is one of the companies approved by EPA to certify equipment used to recover and recycle refrigerants. Technicians should become

familiar with the *Directory of Certified Refrigerant Recovery/Recycling Equipment*, published every March and September by AHRI.

- HVACR equipment certification program. AHRI maintains a certification service, which tests a wide variety of equipment and products to verify the performance described by the manufacturer. Certified directories for various products are published semiannually and annually.

AHRI has a full program of educational activities geared toward helping the nation's vocational and technical schools improve and expand their education and training programs. Under the direction of AHRI's education director and its Education and Training Committee, AHRI serves as a resource for manufacturers, school instructors, department heads, and guidance counselors. In addition to this textbook and its companion materials, AHRI produces the *Bibliography of Training Aids*, a career brochure, and a promotional video for schools to use to recruit students into HVACR programs. Many schools around the country have adopted the ICE competency exams as final exams for their programs. AHRI's most recent efforts involve participation in developing national HVACR competency standards.

Having students pass the ICE competency exams and training toward national competency standards will improve the quality of installation and service. New HVACR technicians will be better prepared, resulting in three basic advantages:

- Limited training required for contractors
- Limited rework or repeat calls due to error
- Limited warranty/replacement for manufacturers

The cost of repeat service calls, which is borne by contractors, may be reduced substantially by employing properly trained technicians. Every new technician receives training and serves as an apprentice for a period of time. That is essentially a period where contractors pay two people to do one job. A properly trained technician will generally require less training time and function sooner than a poorly trained technician.

In co-sponsorship with AHRI, ASHRAE holds an annual international Air Conditioning Heating Refrigeration Exposition, which may draw 30,000 to 50,000 people in the field. Product exhibits, technical displays, and business seminars highlight the event.

American Society of Heating, Refrigeration, and Air-Conditioning Engineers (ASHRAE)

The American Society of Heating, Refrigeration, and Air-Conditioning Engineers (ASHRAE) is an organization started in 1904 as the American Society of Refrigeration Engineers (ASRE) with seventy members. Today its membership is composed of thousands of professional engineers and technicians from all phases of the HVACR industry. ASHRAE also creates equipment standards for the industry. Its most important contribution probably has been a series of our books that have become the reference books of the industry: *HVAC Applications*, *Refrigeration*, *Fundamentals*, and *HVAC Systems and Equipment*.

TECH TIP

Becoming an active participating member in a professional trade association will provide you with an opportunity to continue your HVACR education. The HVACR field is such a dynamic and evolving industry that to stay competitive you must continually attend seminars and take classes. This is a field where your success will depend on your continued education.

American Society of Mechanical Engineers (ASME)

The American Society of Mechanical Engineers is an organization composed of engineers in a wide variety of industries. Among other functions, ASME writes standards related to safety aspects of pressure vessels.

Air Conditioning Contractors of America (ACCA)

The Air Conditioning Contractors of America is a service contractor's association concerned with the education of technicians and service managers with business-improvement techniques. ACCA provides technician EPA certification.

Refrigeration Service Engineers Society (RSES)

The Refrigeration Service Engineers Society is the international professional association for all HVACR workers and is dedicated to education and certification of technicians in the HVACR industry. RSES offers Specialist Certification for senior technicians in eight HVACR areas and has a technician EPA certification program. RSES chapters conduct classroom training in technical areas and are a source for educational printed material and books.

HVAC Excellence

HVAC Excellence is a not-for-profit organization that has been serving the HVACR industry since 1994. The organization's goal is to improve competency through validation of the technical education process by offering progressive levels of technician certification through its HVAC Excellence programs.

SERVICE TIP

The AHRI list of certified equipment is available to anyone through the Internet. This material is very helpful when trying to make a determination of the best equipment to recommend for customers and their specific application needs. On the Web, very often all of the various pieces of equipment are available.

UNIT 1—SUMMARY

Since the beginning of time, people have had a desire to control their environment to live and work more comfortably. That trend will not stop, and that is the good news for anyone entering this ever-growing, financially rewarding, and personally satisfying field. HVACR technicians are required to understand the theories behind designing, installing, and servicing a wide range of systems. This diversity ensures that each day on the job will be new and unique, ever changing, and challenging.

UNIT 1—REVIEW QUESTIONS

1. List some of the different ways that homes and buildings may be heated.
2. What were some of the primary heating fuels that early civilizations used?
3. When is it believed that ice was first artificially made for food storage?
4. How did early man make ice?
5. Why did some manufacturers spray water in factories in the early 1700s?
6. How did early Romans cool palaces?
7. What do the terms *environmental heating* and *air conditioning* refer to?
8. What does the term *process heating and cooling* refer to?
9. When did central warm-air systems for residential and commercial applications become well defined?
10. Who developed what is referred to as modern air conditioning?
11. When did mass air conditioning of homes with window units begin?
12. Why is it important to freeze foods quickly?
13. Why do some businesses and/or local and state governments require criminal background checks for HVACR workers?
14. What size range might a commercial air conditioner fit into?
15. Give an example of some of the types of equipment that a commercial refrigeration technician might work on.
16. What type of things might an entry-level helper do?
17. Whose job is it to do the initial installation process, such as install the refrigerant lines, electrical lines, thermostat and control lines, duct boots, and duct run, as well as setting the indoor and outdoor units?
18. What skills must a service technician have?
19. What are some of the things that a service manager must be able to do?
20. What is the ICE exam, and who might take it?
21. What are some of the RSES's activities?

UNIT 2

Being a Professional HVACR Technician

OBJECTIVES

After completing this unit, you will be able to:

1. list some of the most popular HVACR publications.
2. explain the importance of professional certifications.
3. list the seven specialty areas of NATE specialty certification.
4. explain the value of taking the Industry Competency Exam (ICE).
5. list the items that help make for a professional appearance while on the job.
6. describe how to develop good communication with the customer.

2.1 INTRODUCTION

The air-conditioning and refrigeration industry has more professional organizations, trade associations, publications, and other related organizations than most any other technical field. As a student, you should consider becoming involved with a student organization such as the student clubs of ACCA, RSES, or ASHRAE. These will give you an opportunity to begin developing extremely important business and technical contacts in the local HVACR industry, and these contacts will serve you very well as you enter the profession.

As a professional in the trade, it is to your advantage to maintain a close relationship with one or more of these professional organizations. Each group provides its members with the latest trends and most current technical information. This gives members a significant edge. Most of the organizations provide ongoing technical and business training classes. Many of the classes cover the latest trends in equipment, regulations, codes and standards, local building regulations, and business practices. Being able as a member to participate in these ongoing educational opportunities will keep you at the leading edge of your new profession.

Each of these professional organizations has publications, and many provide the industry with codes and standards. These publications would be an excellent addition to your technical library. Having an up-to-date library will help you provide your employer and customers with the best possible service while making you significantly more valuable as an employee. HVACR is an ongoing learning process for even the most skilled technician.

Figure 2-1 lists a number of these professional associations. Most have Web sites, and many have local, regional, and state chapters that you can become affiliated with.

Many of the HVACR professional organizations have industrial trade shows. These shows provide excellent opportunities for you to see the various manufacturers' latest equipment, tools, supplies, and services. Some of the trade shows are local, others may be regional, some are national, and a few are international (Figure 2-2).

TECH TIP

Once you enter the profession as an HVACR technician, all costs associated with taking additional classes, purchasing books, and membership dues may be tax deductible.

2.2 PUBLICATIONS

Another excellent way of keeping up with the latest information in the HVACR field is by subscribing to one or more of the HVACR publications (Figure 2-3). Some of these publications are weekly, while others are monthly. They all contain well-written articles specifically addressing HVACR industry concerns. Many of them are written to teach their readers troubleshooting skills. Their articles are very valuable even to the skilled technician.

Some of the professional organizations have their own newsletters that are published and provided to their members. Some local and state chapters of these organizations have additional newsletters that are provided to their members.

2.3 PROFESSIONAL CERTIFICATION

Every HVACR technician must become certified under the EPA Section 608 regulations. Compliance with these regulations regarding the management of refrigerants is mandatory for everyone in the trade. Following your successful completion of any and all of the appropriate levels, it remains your responsibility to stay current with any changes in these regulations. As unfair as it may seem, you can be fined significantly for violating an EPA regulation pertaining to refrigerants even if that regulation took effect after your successful completion of the certification. In addition, it is your sole responsibility to remember and follow all of the

2.4 INDUSTRY COMPETENCY EXAM (ICE)

The Air-Conditioning, Heating, and Refrigeration Institute (AHRI); the Air Conditioning Contractors of America (ACCA); Heating, Airconditioning, and Refrigeration Distributors International (HARDI); the Plumbing, Heating, Cooling Contractors Association (PHCC); North American Technician Excellence (NATE); the Partnership for Air-Conditioning, Heating, Refrigeration Accreditation (PAHRA); and the Refrigeration Service Engineers Society (RSES) have established a competency examination that is designed for stu-

dents who have completed or nearly completed a technical training program. This examination is voluntary, but it does provide students leaving a training program, whether from high school, trade school, or community college, with an opportunity to evaluate their knowledge with an industry standardized test.

The ICE has been developed over the years with input from manufacturers, trade associations, instructors, and other industry experts. This exam can also provide your institution with an overall evaluation of its training program. Upon your successful completion of the ICE, your name, along with your school's name, is published and made available to area contractors who might be looking for new skilled employees. In short, the successful completion of the ICE can put you well ahead of other graduates from programs not participating in the ICE. The ICE is in three parts—Residential Heating and Air Conditioning, Light Commercial Heating and Air Conditioning, and Commercial Refrigeration. A good student will make testing and certification achievement a challenge for him- or herself, always setting goals high.

AHRI and its affiliates provide training institutions with incentives as encouragement to participate in the ICE by directing many of its manufacturing members' equipment donation programs toward the schools, institutes, and colleges that participate in the ICE program. These equipment donations can become an excellent source of the latest equipment you will be seeing in the field.

2.5 SKILLS USA

Skills USA is a vocational industrial club for students in high schools, trade schools, and community colleges. Skills USA clubs are open to students in all areas of specialty, including HVACR. The national organization provides local chapters and students with many opportunities to develop leadership, citizenship, and interpersonal skills that are invaluable to the success of individuals in any profession. The Skills USA logo is shown in Figure 2-4a.

In addition to the opportunities for individual professional growth, Skills USA sponsors regional, state, national, and international skills competitions. The contestants for the HVACR competitions will be tested in the following areas: written

(a)

(b)

(c)

Figure 2-4 (a) Skills USA logo; (b,c) Students competing in the National Skills Olympics.

exam, brazing skills, refrigerant component service, air measurement and troubleshooting, refrigerant recovery, and electrical troubleshooting. Various industry equipment used may include ice machines, refrigerated display cases, small package HVAC units, furnaces, and split-system air-conditioning units. These skills competitions are available on the secondary and post-secondary levels. By participating in the competition, students are given the opportunity to demonstrate their troubleshooting skills in diagnosing real-world problems under the supervision of highly skilled individuals serving as judges.

The winners of local, state, and national competitions move on to the international skills competition held in a different country each year. At the international competition,

the best and brightest students from around the world compete to see who has the greatest knowledge and expertise in each of the technical areas, including HVACR. Every student who participates in these skills Olympics at any level receives recognition. Students involved in this program are shown in Figure 2-4b, c. This recognition is invaluable to the students because prospective employers value such recognition.

2.6 COUNCIL OF AIR CONDITIONING AND REFRIGERATION EDUCATORS (CARE)

The Council of Air Conditioning and Refrigeration Educators (CARE) is an organization that was founded in the late 1990s by a group of air-conditioning educators, counselors, and administrators responsible for the various aspects of HVACR training. This group is made up of individuals from secondary schools, post-secondary schools, and colleges, representing institutions from various regions of the country.

The purpose of CARE is to educate to meet or exceed the needs of the industry.

CARE membership is open to instructors, counselors, and administrators who are involved in some aspect of HVACR training. Through this organization, individuals can come together to learn and share experiences for the betterment of the HVACR students and program.

2.7 NORTH AMERICAN TECHNICAL EXCELLENCE (NATE)

NATE is an independent, third-party certification body formed in 1997 as a result of a concern expressed by many in the industry that there was not a way of distinguishing quality, highly skilled HVACR technicians from every other person working in the field. NATE is supported by all of the major equipment manufacturers, major component manufacturers, professional and trade associations, and the National Skills Standard Board. Figure 2-5 shows a technician with a patch showing NATE certification working on a system. You can earn installation, service or senior certification in one or more of the following specialty areas:

1. Air conditioning
2. Air distribution
3. Air-to-air heat pumps
4. Gas furnaces
5. Oil furnaces
6. Hydronics gas
7. Hydronics oil
8. Light commercial refrigeration
9. Commercial refrigeration
10. Ground source heat pump loop installer
11. HVAC efficiency analyst (Senior Level)

Installation certification is primarily designed for the technician who is involved with the installation or removal of HVAC equipment. Installers assemble the system and fabricate the necessary connections to complete an efficient system. They also set up the operational controls under the supervision of a service technician. After the system is started, the installation technician records the readings for temperature, pressure, voltage, current, and any other

Figure 2-5 NATE-certified air-conditioning technician checking the refrigerant charge in a residential system.

measurements required by the manufacturer or service company for the completion of the warranty paperwork.

The service technician must have all of the skills of the installation technician plus be able to work independently. Service technicians must be able to perform field diagnostics to determine the cause of system failures and to make the needed repairs.

In addition to having the technical skills required to pass the various areas of specialization, each technician must take a core exam as part of the exam process. The core test covers basic math, customer relations, comfort, heat transfer, and the fundamentals of electricity. A well-trained, experienced technician should be able to take and pass both the core and area specialty exams. A number of organizations provide NATE pretest tutorial classes to bring technicians' skill levels up to pass the exam. The exam passing score is 70 percent or better. Certification lasts for five years, after which time a technician must recertify. There are many classes that qualify for credits that can be used toward recertification. If a technician receives 60 hours of credit, the technician does not have to take a test at five years. If the technician obtains 30 credit hours, he or she will only be required to take a fifty-question specialty test instead of a hundred questions.

NATE recommends that you have at least one year of field experience before taking an installation series test and at least two years of experience before taking a service series test. It is further recommended that you have some instruction from an educational institution or trade association.

NATE has provided technicians with Knowledge Areas of Technician Expertise (KATES), which give detailed outlines of all of the material that a technician can expect to

be questioned about on an exam. These KATES represent all of the knowledge and skills that a quality HVACR technician should have. The KATES also help the prospective test candidate to focus on those areas that the industry feels are most important.

2.8 HVAC EXCELLENCE

HVAC Excellence established the national standards for HVACR programs in the summer of 1999, becoming the industry's first accrediting body. Programmatic accreditation is an independent third-party review of an educational program. This begins with experienced auditors conducting an on-site visit at each school applying for accreditation. The process validates that established standards of excellence for HVACR educational programs are met. Standards require a thorough examination of mission of the program, administrative responsibilities, finances and funds, curriculum, plan of instructions, facilities, equipment and tools, cooperative training, and instructor's qualifications.

2.9 CODES AND STANDARDS

There are many organizations and agencies that provide codes that are used throughout the HVACR industry, and Figure 2-6 lists many of them. In addition to codes, these groups provide standards. The difference between a code and a standard is that codes often carry with them the force of law, and standards do not. Organizations providing standards to the HVACR industry are listed in Figure 2-7.

Many consumer groups over the years have worked with HVACR industry leaders to help the industry provide consumers with the most efficient and effective service. Some of these consumer information groups are listed in Figure 2-8.

2.10 THE PROFESSIONAL TECHNICIAN'S APPEARANCE

As a service technician you are seen by the customer as a representative of your company. Customers often assume the appearance and professionalism of the technician is a reflection on the technician and company's technical skills. It is therefore important that you present yourself professionally, in a very clean and neat manner, to the customer. In some cases you might find during the course of the day that your uniform becomes soiled. It is therefore a good idea to carry at least an extra clean shirt in the service van so that you can change if necessary.

If your company does not provide uniforms, you should dress appropriately. In some cases, blue jeans and a jersey or denim shirt are acceptable. In other cases, where you might be working in an office building, slacks and a shirt would be appropriate. Check with your employer to see what the company dress code is. In addition to your clothing, you must have a clean and neat personal appearance. That means clean, well-kept hair and either being clean shaven or having a well-kept beard for men, and clean hands for everyone.

You must keep your service vehicle clean and neat. It is a rolling billboard for your company, and it is important that it look sharp. A clean service van provides a better, more efficient work area, making it easier to find tools and supplies, and it also makes a better impression on the customer. Unless you have permission from residential customers, you should not park your service vehicle in their driveway. Always make it a habit to park your vehicle on the street. You do not want to be responsible for cleaning up an oil spill, and your vehicle can obstruct their access, which to some customers is very aggravating.

When you present yourself to a customer's door, you should have your hands in plain sight either at your side or holding your tools and clipboard. When the customer opens the door, if you take one step back, it will give the customer a greater sense of comfort. Many companies provide photo ID badges, and you must have yours clearly displayed. If it is necessary for you to enter a dwelling for service, ask permission from the homeowner before entering.

2.11 WORKING NEAT

Some companies provide technicians with paper shoe covers to prevent tracking dirt into residences. If you suspect your shoes are dirty, either remove them or use the covers. You and your company can be responsible for cleaning the carpet if it becomes soiled. When working on an indoor furnace, place a drop cloth on the floor in front of the furnace so that any debris will be contained. When you are finished working in the furnace area, a small battery-powered vacuum cleaner can be used to pick up loose dirt and debris in the area. Use a damp rag to wipe down any fingerprints that are on the equipment or that may be on the door or woodwork.

TECH TIP

Cleaning up the equipment area in a residence is an excellent PR move. You should vacuum up all of the debris in the area. Many customers judge your work by appearance, and all they may understand is neat and clean. When changing out a unit, electricians or plumbers may also be involved. You should clean up any mess even if you did not make it. Leaving behind a mess will reflect on you, since the final repair is still your responsibility.

In many residences, the air handler is located in an attic. If access to the unit is through a pulldown staircase, make certain that any dirt or debris that falls from the

stairs when it is pulled down is cleaned up. If you are going to be going in and out of the attic a number of times during the service, place a drop cloth on the floor below the stairs to catch any insulation or other debris that might fall on the floor. Do not attempt to carry a large number of tools up and down the stairs. This can cause you to be caught off balance and possibly drop your toolbox. In addition, most attic stairs have a weight limit that could be exceeded by you and a large toolbox. Attic stair treads, like any ladder, are strongest next to the side rail. For that reason, when you ascend and descend the stairs, place your foot as close as possible to the side next to the side rail to reduce the possibility of breaking the stairs. Always be careful in an attic so that you do not step through the homeowner's ceiling.

Many customers have extensively landscaped their homes, including the area around an outdoor condensing unit. Even though their landscaping may encroach within the manufacturer's recommended free air space around the unit, do not remove this landscaping. Notify the homeowner as to how it should be trimmed so that they or their landscaper can remove the vegetation. When working around vegetation, it is important that you be as careful as possible so as not to damage any plants. On very soft, wet ground your repeated trips to the service van can wear a path. To avoid this, each time you have to cross soft, wet ground, take a slightly different route when possible.

It is considered bad practice to leave packaging and boxes left over from the installation of new equipment in the customer's trash receptacles. This material should be taken with you so as not to overload their receptacle.

TECH TIP

Working in air conditioning and refrigeration is often a very hot job. From time to time customers may offer you a glass of water, tea, or cold drink. Use your discretion on accepting these offers. However, it is never appropriate for you to accept a beer or other alcoholic beverage from a customer. Even if you do not open the drink but take it with you, you have significantly damaged your credibility with the customer and your boss. If you take a beer, even though you do not drink it, and there is a problem with the service you provided the customer, the first thing the customer is going to tell your boss and everyone else is that you were drinking on the job, in spite of the fact that they gave you the beer. *Do not take any alcoholic beverages that are offered by customers.*

2.12 TECHNICIAN AND CUSTOMER COMMUNICATION

A large part of the technician's job is to educate the customer as to the problem that was found and the available options for its repair. Tell the customer what failed, why it failed, and the options to fix the problem. Do not simply tell the customer that they need a part and that you are going to replace it.

Many customers would like an estimate of the job's cost. In some municipalities you are obligated under consumer protection laws to provide customers with such a quote. In some cases the quote must be in writing. If, however, as part of your service you uncover a situation that could not have been foreseen or was not visible in your initial evaluation that will require additional work, immediately stop and inform the customer of the new problem. Do not simply make the repairs and expect the customer to accept the higher charge at the conclusion of the job.

TECH TIP

If you locate an additional problem or pending problem with a customer's system and, after notifying the customer of your concerns, they choose not to have you provide that repair, you should note that on the customer's invoice as part of your service call recordkeeping and get them to sign the acknowledgment.

Under no circumstance should you tell a customer that the previous technician messed up their system when they did the last service. All that will result from such statements is the loss of faith the customer may have in you and your professionalism; but, more important, you might find out that one of your colleagues who works for your company did the last service job.

TECH TIP

Good professional technicians never knock the competition. Their skill and knowledge will set them apart from everyone else without the need to brag.

One of the primary complaints customers have on any service call is punctuality. It is not always possible to be at a job exactly when you anticipated being there, as earlier service calls may take more time than you initially estimated. However, as soon as you realize you are not going to make the schedule, and as early as possible, let the customer know and give them an opportunity, if they so choose, to reschedule. If you do reschedule, you must be at the next scheduled appointment on time.

It is also extremely important that you provide a very clear, clean, and legible invoice or bill to the customer. If it is necessary for you to get prices, look up information, or check your spelling, you should do all of that in your service vehicle and not in front of the customer. Even though you may not be a literary expert, customers do expect you to provide them with clear, concise, well-written statements. If you have a problem writing clear and concise statements, you may want to invest in a PDA (personal digital assistant) device. There are many of these devices on the market, and many can have spell-check and writing programs installed.

TECH TIP

Some air-conditioning and refrigeration work in the summer requires that the technician work in relatively hot environments such as attics or buildings without working air-conditioning systems. To prevent heat stress injury, it is important that you guard against dehydration by drinking large quantities of water or sports drinks. You must drink enough so that you have to use the restroom at least once every couple of hours throughout the day. In addition to dehydration, you may also develop kidney and bladder problems if you do not drink enough fluids while working in hot environments.

Carbonated beverages, milk, fruit juice, beer, and many other beverages do not replace the body's electrolytes. Without replacing the electrolytes, you can feel fatigue and may experience cramps. For that reason, only sports drinks with the essential electrolytes and water are recommended as your primary drinks when working in the heat.

UNIT 2—SUMMARY

You should become familiar with the various professional organizations and trade associations that support the air-conditioning and refrigeration industry and consider joining those that are suitable to your career goals. Read the many available publications so that you may keep up-to-date with the latest changes in industry practices and standards.

As a refrigerant technician, you must become certified under EPA Section 608 regulations. To further demonstrate your ability as a service technician, you may also consider taking an industry standardized test such as the Industry Competency Exam (ICE). There are also certification programs such as North American Technical Excellence (NATE) that allow you to focus on specialty areas.

Always remember to present yourself to the customer as a neat and clean professional. Carry an extra set of clothes in the event you need to change because your uniform becomes soiled. Think of using paper shoe covers rather than tracking dirt across the customer's carpet. Finally, always be polite to the customer and make sure

that you communicate clearly. A large part of your job is to provide guidance for the customer by explaining the nature of the equipment-related problem. Be prepared to tell the customer what failed, why it failed, and the options to fix the problem.

UNIT 3

Safety

OBJECTIVES

After completing this unit, you will be able to:

1. explain how to work safely to avoid accidents.
2. discuss the material that appears on all Material Safety Data Sheets (MSDS).
3. discuss how to safely use hand and power tools.
4. discuss how to practice safety in the shop.
5. describe four types of fire extinguishers.
6. demonstrate a safe method of lifting heavy objects.
7. discuss safe welding and cutting practices.
8. discuss electrical safety rules.
9. discuss the safe use of refrigerants, their storage, and proper disposal.
10. tell how to safely handle refrigerant cylinders.
11. discuss refrigerant system safety.
12. name three major hazards of pressure vessels.
13. discuss how a technician's driving record can affect employability.
14. tell what steps should be followed in case of an accident.

3.1 INTRODUCTION

In every trade, safety is a major concern, and safety is everyone's first job responsibility. Accidents, no matter how minor, can cost the technician, the company, and the customer unnecessary losses of time and money. There is no reason to feel that accidents are inevitable and something you must just accept. Good working habits, good tools, and being vigilant to potential hazards can virtually eliminate accidents. Never do anything you feel is unsafe. When working with new equipment or tools, read all the safety instructions and follow them.

Most companies require some type of safety training for all their employees. In addition, some of the businesses where you may be asked to do HVACR work at may have their own safety program that you must pass before beginning work at their site.

Most accidents are caused by carelessness, as well as lack of awareness of proper safety procedures. This unit deals with some of the basic safety tips and procedures the installer and service technician should follow—whether on the job site or at related locations where hazards could exist; additional specific safety facts are covered in each unit. Read and follow all safety rules.

3.2 PERSONAL PROTECTIVE EQUIPMENT

Personal protection equipment (PPE) is designed to reduce your exposure to hazards that cannot be eliminated or controlled. PPE may include equipment or devices to protect your head, face, eyes, ears, respiratory system, hands, and feet. Some devices, such as safety glasses, are commonly used, while others, such as respiratory protection, may be less frequently used.

If PPE is required for any job, OSHA (Occupational Safety and Health Administration) recommends that all employees

be trained. This training may be as short as a few minutes or as long as several hours or more. The length of the training time depends on the level of hazard and the complexity of the PPE to be used.

Keeping all PPE clean and in good working condition is essential to ensure that, when needed, it will work properly.

Head Protection

An approved hard hat (Figure 3-1) should be worn whenever there is a danger of things dropping on the head or where the head may be bumped. On a construction site, proper safety head gear is a must.

Eye and Face Protection

The majority of eye injuries are the result of flying or falling objects. Most of these objects are smaller than the head of a pin but can cause serious injury. Approved eye or face protectors (Figure 3-2) must be worn whenever there is

Figure 3-1 Hard hats are required to be worn on many job sites.

Figure 3-2 Eye protection equipment: (a) these safety goggles can be worn over glasses; (b) safety glasses with side protection.

a danger of objects striking the eyes or face. Side shields must be part of any safety glasses worn, even if they are prescription eyeglasses. Safety glasses or goggles must be worn over prescription eyeglasses if they do not have side shields. Eye and face protectors come in various shapes and sizes, and some of them are very specialized.

Special eye protectors must be worn when arc welding, spot welding, and burning to cut out harmful light radiation. These special face visors come with various shades of viewing eyepieces that filter out the harmful emissions. Take time to identify the right one for the job. For example, never wear oxyacetylene welding goggles when an arc welding face shield is needed.

Confine long hair and loose clothing before operating rotating equipment.

TECH TIP

To control insurance costs, many air-conditioning companies have adopted very stringent policies on personal protection equipment. Unlike your shop teacher, who may have reminded you each day about safety glasses, ear protection, and so on, many employers may terminate you with a single safety infraction. Others may warn you once or twice about wearing proper safety equipment while working. But no HVACR companies are going to give you unlimited warnings before your employment with them is terminated. These policies are good for you and the company, because they reduce the likelihood of your being injured on the job.

Ear Protection

Hearing protection devices (Figure 3-3) must be worn whenever there is exposure to high noise levels of any duration. These devices are of two types: (1) ear plugs, which are inserted in the ear, and (2) headphones, which cover the ear. Either one must be properly selected on the basis of how much protection is required.

Respiratory Protection

There are two main types of respirators, as shown in Figure 3-4: (1) *air-purifying respirators* are ones that purify the air by filtering out harmful dust, mist, metal, fumes, gas, and vapor; and (2) *atmosphere-supplying respirators* are

Figure 3-3 Ear protection equipment: (a) disposable earplugs on a lanyard (that fits around the neck) allow for easy removal and reuse; (b) headphones protect both ears and hearing; (c, d) disposable, one-time-use earplugs.

Figure 3-4 Filtration masks: (a, b) light-duty filter; (c) respirator with replaceable filters.

ones that supply clean breathing air from a compressed air source. The second type should always be worn when working in a confined space where concentrations of harmful substances are very high or where the concentration is unknown. Remember that most refrigerants are odorless, tasteless, and invisible and can cause asphyxiation in a very short time.

Respirators must fit tightly against the skin so that there is no leakage from the outside into the face. Workers who are required to use respirators at any time must be instructed in their use, care, maintenance, and limitations.

TECH TIP

Respirators are required to be located in all equipment rooms where that equipment contains large quantities of refrigerant. These respirators are provided in case there is a massive refrigerant leak. If you work in one of these areas, you must familiarize yourself with where the respirators are located and how to quickly put them on. You may have only a matter of seconds once a refrigerant leak alarm is sounded to safely put on this equipment.

Hand, Foot, and Back Protection

There are many different kinds of gloves used for hand protection, as shown in Figure 3-5. Some are made for special uses, such as gloves of steel mesh or Kevlar to protect against cuts and puncture wounds. Different glove materials are needed to protect against a variety of different chemicals. Choose the right kind from a dependable sup-

Figure 3-5 (a) Gauntlet-type work gloves; (b) work gloves; (c) welding gloves; (d) open-tipped gloves.

Figure 3-6 High-top work boots.

plier who can supply information to lead you to the right gloves. Discard any damaged ones.

Lifting heavy objects improperly can lead to back injury. Always bend at the knees and lift straight upward rather than bending over, which will place undue stress on the spine. There are a number of different types of back-support belts available. These should be used if heavy lifting is expected to be performed on a regular basis.

When choosing foot protection, as shown in Figure 3-6, use the following guidelines:

1. All footwear must be well constructed to support the foot and to provide secure footing.
2. Where there is danger of injury to the toes or top of the foot or from electrical shock, the proper shoe or boot, such as steel toe, must have Construction Safety Approval (CSA) indicated.
3. Where there is danger of injury to the ankle, footwear must cover the ankle and have a built-in protective element/support.
4. If there is danger of harmful liquids spilling on the foot, the top of the shoe must be completely covered with an impervious material or treated to keep the dripped substance from contacting the skin.

3.3 LADDERS AND SCAFFOLDS

Access equipment refers to ladders and scaffolds that are used to reach locations not accessible by other means. The following precautions should be practiced in the use of ladders.

1. Only use CSA- or ANSI-approved ladders. Maintain ladders in good condition, and inspect ladders before each use. Discard ladders needing frequent repairs or showing signs of deterioration.
2. All portable ladders must have no-slip feet.
3. Place ladders on a firm footing, no farther out from the wall than one quarter of the height required, as shown in Figure 3-7.
4. Ladders must be tied, blocked, or otherwise secured at the top where the ladder meets the building to prevent them from slipping sideways.

Figure 3-7 A ladder must be placed so the top is at least 3 ft above the roof and at an angle in which the distance from the building is one-fourth the height of the building.

5. Never overload a ladder. Follow the maximum carrying capacity of the ladder, including the person and equipment. The American National Standards Institute (ANSI) sets the standard for ladders.
6. Only one person should be on a ladder, unless the ladder is designed to carry more people. Follow maximum load rating.
7. Never use a broken ladder. Never place a ladder for use on top of scaffolding, and never use a borrowed ladder on someone's property. Always use your own ladder even if you need to leave the job site to go get it.
8. Always face the ladder and use both hands when climbing or descending a ladder.
9. Use fiberglass or wood ladders when doing any work around electrical lines (Figure 3-8).
10. Ladders should be long enough so you can perform the work comfortably, without leaning or having to go beyond the two rungs below the top rung safety barrier.
11. Stepladders should only be used in the fully open position.

Figure 3-8 Never use a metal ladder near electrical wires!

CAUTION

Ladders must be inspected from time to time to ensure their safety. Some companies will require that a company safety official inspect the ladders you carry on your service van. Damaged or worn ladders must be repaired or removed from service.

The following recommendations apply to scaffolds.

1. Scaffolds must be supported by solid footings.
2. A scaffold having a height exceeding three times its base dimension must be secured to the structure.
3. When rolling scaffolds are used, the wheels must be locked when there are workers on the scaffold.
4. No worker is to remain on the scaffold while it is being moved. All equipment should also be removed before moving a scaffold.
5. Access to the work platform must be a fixed vertical ladder or other approved means.

3.4 FALL PROTECTION

Two types of equipment for preventing injury from falling are (1) fall-prevention equipment and (2) fall-arresting equipment. Either of these methods is required when working at heights over 10 ft above grade when no other means has been provided for preventing falls. Figure 3-9 illustrates a safety belt.

In fall prevention, a worker is prevented from getting into a situation where a fall can occur. For example, a safety belt attached to a securely anchored lanyard will limit the distance a worker can move.

In fall arresting, the worker must wear a safety harness attached to a securely anchored lanyard, which will limit the fall to a safe distance above impact. The harness helps prevent the worker from suffering internal damage. Belts should not be used to arrest a fall because they do not provide the measure of safety that harnesses do. Where a fall-arresting system is not practicable, a safety net should be suspended below the work activity. The worker should be secured separately from the tools and equipment.

Figure 3-9 Safety equipment for heights over 10 ft above grade—a safety lanyard would be attached to this safety belt.

CAUTION

Fall-protection harnesses are designed to suspend you in a vertical position if you accidentally slip and fall from a height. These harnesses, however, are not designed to suspend you for long periods of time. In recent years, workers have survived a fall, only to die in the safety harness. The safety harness can constrict blood flow to your legs as you dangle at the end of the safety line. The restriction of blood flow to your legs can cause enough blood to pool in your legs so that you might pass out or even die if allowed to dangle motionless for a long period of time. If you are the victim of a fall and are suspended on your safety line, you should remember to move your legs to help keep the blood flowing until you are rescued.

3.5 HOT AND COLD

HVACR technicians often work with extremely hot or extremely cold vapors, liquids, and solid objects. Similar PPE is required for both extremely hot and extremely cold work because of the potential for burns. Burns can occur on your skin from accidentally contacting either extremely hot or extremely cold material. It is easy to see how a hot material can cause a burn but more difficult to see how something that is cold can burn your skin.

When you touch something that is extremely cold, your body heat is drawn out so quickly that it causes the surface of your skin to burn and blister. Remember that refrigerant will cause frostbite, so be careful.

3.6 HARMFUL SUBSTANCES

Workers in the mechanical trades can be exposed to a variety of harmful substances, such as dust, asbestos, carbon monoxide, refrigerants, resins, adhesives, and solvents.

All dust can be harmful. Where dust cannot be controlled by engineering methods, an approved respirator designed to filter out specific dust must be worn.

When asbestos-containing material (insulation) is being cut or shaped, the particles must be removed by a ventilation system that discharges the particulate matter through a

high-efficiency particulate air (HEPA) filter. All waste materials that contain asbestos must be placed in impervious bags for transfer to an approved disposal site. These fibers, when inhaled, are considered carcinogenic. If you are asked to remove asbestos from, for instance, a piece of equipment such as an old boiler, do not attempt this. You do not want to put anyone's life at risk, so do not be forced into improperly removing asbestos. Improper removal of asbestos can also lead to serious fines.

Engine-driven mobile equipment operating in an enclosed area can produce dangerous levels of carbon monoxide (CO). Oil-fired or gas-fired space heaters without suitable vents can also produce carbon monoxide. Areas must be well ventilated while being heated with these devices.

TECH TIP

Read and follow all label safety and user instructions on any materials you use in the HVACR field. Some of these materials can be hazardous to your health if you do not follow the label's directions.

Some refrigerants are more dangerous than others, but all refrigerants are dangerous if they are allowed to replace the oxygen in the air. Even the so-called safe refrigerants can produce a poisonous phosgene gas when heated to high temperatures, and refrigerants sprayed on any part of the body can quickly freeze tissue.

Resins, adhesives, and solvents can be dangerous if not properly handled. Ensure that the workspace is continuously ventilated with large amounts of fresh air.

Never use carbon tetrachloride for any purpose, because it is extremely toxic, either inhaled or on the skin. Even slight encounters with it can cause chronic problems.

To provide workers and health-care professionals with specific reactions and treatments for exposure to materials on the job, all manufacturers must provide, on request, a Material Safety Data Sheet (MSDS) on all of their products. It is your responsibility to request a MSDS for all of the products you work with or carry on your service vehicle. Some site safety officers, building inspectors, or job managers may even ask to see the MSDS before you are allowed to start or continue work.

3.7 MATERIAL SAFETY DATA SHEETS (MSDS)

Material safety data sheets are required by law and have specific important information listed in specific areas so that emergency personnel can easily read them. If an area does not apply to the product, the manufacturer must mark the space as being nonapplicable. No blank spaces are allowed on a MSDS. This is done so that there will not be any confusion regarding the safety or reactions to any products. You should read the MSDS on any material before you use it so you know how to use it properly and safely and know what to do if there is an accident involving the material.

Figure 3-10 is an example of an MSDS for a coil cleaner. The following material will appear on every MSDS:

4. **HMIS Information.** The information in this section refers to the hazardous material identification system (HMIS). This information provides health-care workers with a relative number according to how significantly the material will affect health, how reactive it is, and its flammability.
5. **Section III: Physical/Chemical Characteristics.** This section gives the properties of the material, such as its boiling point, vapor pressure, solubility in water, specific gravity, melting point, evaporation rate, and its appearance or odor.
6. **Section IV: Fire and Explosion Hazard Data.** Gives the flammability of the material and lists its flash point, flammability limits, extinguishing media, any special firefighting procedures, and any unusual fire or explosion hazards.

In addition to the information on the MSDS, you must read and follow all manufacturers' listed instructions for

proper use and handling of every material you use on the job. Many companies have policies that require that you be fired if you do not follow these instructions. These policies are both for your protection and for the protection of the company and the customers. Handle all material properly according to the manufacturer's instructions.

SERVICE TIP

It is a good work practice to request a MSDS on all products that you get from the supply house. Some job site safety officials require that you have a MSDS on all of the products you will be using at their job site. An easy way of maintaining these documents is to put them all in a large manila envelope that is labeled MSDS and keep this envelope in your service vehicle.

3.8 SAFE WORK PRACTICES

The installer and service technician works in many areas: in the shop, in various types of buildings, in equipment rooms, on rooftops, under houses, and on the ground outside buildings. Each location requires different activities where safe performance is essential.

In addition, the worker deals with many potentially dangerous conditions, such as handling pressurized liquids and gases, moving equipment and machines, working with electricity and chemicals, and being exposed to heat and cold. It is important, therefore, that the technician practice good safety procedures wherever or whatever the work is.

Confined Space Entry

A confined space is an area that has been closed off from any outside source of ventilation and is a space large enough for a person to enter and perform work. Entering a storage tank through a manhole opening would be an example of this. Never enter such a space unless the atmosphere has been checked to ensure that no hazardous vapors exist. Even without the presence of hazardous vapors, the space could be potentially deadly due to a lack of oxygen. A person entering an oxygen-deficient space may not realize it until too late and suddenly pass out unconscious. Never enter a confined space until the air quality in the space has been verified as acceptable. Even then, always leave someone standing outside the space with emergency breathing apparatus available and ready.

3.9 TOOLS

All tools come with safety instructions. Do not assume you know how to use a tool; read and follow the manufacturer's safety instructions. These instructions have been developed and tested to ensure that, when followed, you are not likely to be injured.

Part of the manufacturer's literature may include instructions on how to service or repair the tool. Make sure to follow these instructions so that your tools will last longer and you can use them safely.

Hand Tools

1. Keep all hand tools sharp, clean, and in safe working order.
2. Defective tools should be repaired or replaced.
3. Use correct, proper fitting wrenches for nuts, bolts, and objects to be turned or held.
4. Do not work in the dark; use plenty of light.
5. Do not leave tools on the floor. Keep them properly put away neatly in your vehicle.

Power Tools

1. Only use power tools that are properly grounded.
2. Stand on dry, nonconductive surfaces when using electrical tools.
3. Use only properly sized electrical cords in good condition with a GFI or GFCI.
4. Turn on the power only after checking to see that there is no obstruction to proper operation.
5. Disconnect the power from an electrical tool (or motor) before performing any maintenance.
6. Disconnect the power supply when equipment is not in use.

CAUTION

Never use portable electrical equipment unless it is connected to a ground fault circuit interrupter (GFCI) or ground fault interrupter (GFI). GFI is the term that is sometimes used when referring to a GFCI. A GFCI is a safety device that cuts off electric current to a circuit when a short or ground is detected. These devices are designed to prevent burns and electrocution if a portable electric tool is being used. OSHA requires that all extension cords used for outside service work be equipped with GFCIs. Some extension cords now come with these devices built into the plug. If your extension cords do not have GFCIs built in, one can be purchased and added to the end.

3.10 SHOP SAFETY

1. Keep the shop or laboratory floor clear of scraps, litter, and spilled liquid.
2. Store oily shop towels or oily waste in metal containers in an open, airy place.
3. Clean the chips from a machine with a brush; do not use a towel, bare hands, or compressed air.
4. Keep safety glasses and gloves in a prominent location adjacent to machinery used for grinding, buffing, or hammering and where material with sharp edges is handled.
5. Establish cleaning periods regularly, at least on a daily basis. Make sure everyone is clear when using compressed air to clean.

Maintaining an Orderly Shop

Proper organization of machinery and equipment in the shop helps to promote safety. In addition, there will be

less wasted time searching for the required tools or materials. Organizing and preparing is often as important as doing the job itself.

1. Arrange machinery and equipment to permit safe, efficient work practices and ease in cleaning.
2. Materials, supplies, tools, and accessories should be safely stored in cabinets, on racks, or in other readily available locations.
3. Working areas and workbenches should be clear. Floors should be cleaned on a daily or more frequent basis. Keep aisles, traffic areas, and exits free of materials and obstructions.
4. Combustible materials should be properly disposed of or stored in approved containers.
5. Drinking fountains and wash facilities should be clean and in good working order at all times.
6. Eyewash stations should be periodically tested to make sure that they work properly, and they should not be blocked and should always be readily accessible.

Fire Extinguishers

The danger of fire is always present. Rags soaked in oil, grease, or paint can ignite spontaneously. Keep used rags in tightly closed approved metal containers.

Sparks, open flames, and hot metal can ignite many materials. Always have a fire extinguisher close at hand when welding or burning.

Extreme caution should be taken with highly flammable and volatile solvents. Due to its low flash point (the temperature at which vapors will ignite), gasoline should never be used as a cleaning solvent.

Fire extinguishers should be readily accessible, properly maintained, regularly inspected, and promptly refilled after use. Fire extinguishers are classified according to their capacity for handling specific types of fires (Figure 3-11).

1. **Class A extinguishers.** These are used for fires involving ordinary combustible materials such as wood, paper, and textiles, where a quenching, cooling action is required.

2. **Class B extinguishers.** These are for flammable liquid and gas fires involving oil, gas, paint, and grease, where oxygen exclusion or flame interruption is essential.
3. **Class C extinguishers.** These are for fires involving electrical wiring and equipment where nonconductivity of the extinguishing agent is critical. This type of extinguisher should be present whenever functional testing and system energizing take place.
4. **Class D extinguishers.** Some metals, such as magnesium, can actually catch fire. Class D extinguishers are used to put out combustible metal fires.

CAUTION

Having the proper fire extinguisher is not enough if it is not large enough to do the job. Make sure that your fire extinguisher is large enough to handle the size of fire that might occur in your work area. If there are a lot of combustible materials, you need a bigger fire extinguisher. In some cases you may want to have more than one fire extinguisher available.

Material Handling

Use mechanical lifting devices whenever possible. Use a hoist when lifting tools or equipment to a roof. If you are required to lift a heavy object, get help. To avoid straining your back, the following procedures should be observed when lifting heavy objects.

1. Bend your knees and pick up the object, keeping your back straight.
2. Gradually lift the weight using your leg muscles, continuing to keep your back vertical.

3.11 WELDING AND CUTTING

Welding and cutting are specialized skills that require special training. Many refrigeration and air-conditioning technicians require this training due to the need to perform some of these operations as part of their work. It must be recognized, strictly from a safety standpoint, that this work should not be attempted without adequate knowledge and instruction.

Acetylene

Acetylene gas under high pressure is unstable, so to make it safe to use it is absorbed in acetone inside the acetylene cylinder. However, an acetylene cylinder can explode if it is struck or jarred severely, so keep the cylinders secured so they cannot be accidentally knocked over or fall. Because acetylene can explode at high pressures, it is illegal to operate a torch with an acetylene pressure greater than 15 psi. For HVACR work, we generally use pressure less than 5 psi. Most acetylene gauges have a red mark indicating 15 psi (Figure 3-12).

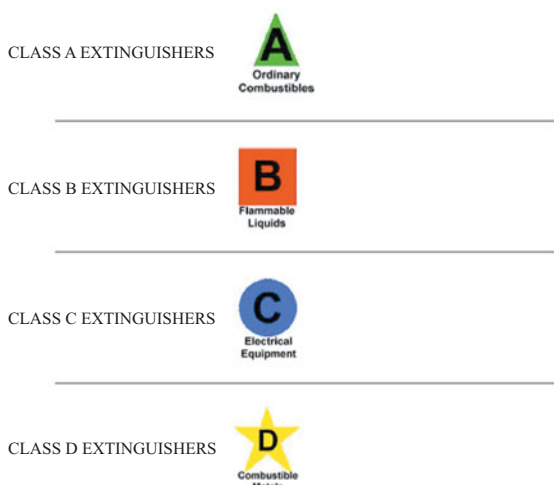

Figure 3-11 Fire extinguisher classification symbols.

Figure 3-12 Acetylene regulator with gauges.

CAUTION

The acetone used to stabilize the acetylene is absent in the neck of the tank. For this reason, never store or transport an acetylene cylinder in the horizontal position. Storage in this manner even for short periods is very dangerous.

Oxygen

Oxygen is provided in highly pressurized cylinders. A full oxygen cylinder contains approximately 2,000 lb/psi of oxygen. Because the oxygen is under such great pressure, care must be taken to ensure that the oxygen cylinder valve is not damaged or knocked off. If the oxygen cylinder valve were to be broken off of a full oxygen cylinder, the cylinder could fly around the room much like a child's balloon. To prevent possible damage to the valves and regulators on oxygen and acetylene cylinders, the cylinders should be securely attached to a frame or cart when they are in use (Figure 3-13).

CAUTION

Certain materials react explosively if exposed to high-pressure pure oxygen. Never use oil or grease on any part of the oxygen or acetylene regulator, hoses, or torch and tips. Ensure that all fittings are clean and dry when assembling. Repair using only manufacturer-approved replacement parts.

Air acetylene torches are used by HVACR technicians to produce sufficient heat for silver (hard) soldering brazing. These torches use a mixture of air and acetylene as a fuel.

Figure 3-13 Portable oxyacetylene welding and cutting rig. (Courtesy of Victor, a Brand of Thermadyne Industries, Inc.)

Oxyacetylene torches are used for brazing, welding, and cutting. These torches mix oxygen and acetylene gases to produce a very intense, hot flame.

The following safety rules should be practiced when using this equipment.

1. Always use a welding regulator on acetylene and oxygen cylinders.
2. Never use oil or grease on a regulator, as this could cause a violent explosion with compressed oxygen.
3. Always secure the cylinder to something solid to prevent it from being accidentally knocked over.
4. Wear the proper colored safety glasses.
5. Open the valve on the acetylene cylinder only one and one-quarter turns.
6. Light the torch with a striker.

SAFETY TIP

Always remove regulators from oxygen and acetylene cylinders before you put them back in your service vehicle. In many states and cities it is against the law to transport oxygen and acetylene cylinders in a motor vehicle with the regulators attached. The danger is that in an accident the regulators could be broken off, causing a fire or explosion.

CAUTION

All oxygen and acetylene cylinders should be stored and used in secure racks or carts. Federal safety regulations (OSHA) require 55-ft³ cylinders and larger to be safety chained to carts or structures anytime the cylinder is being used with its safety cap removed. There are no exceptions to these OSHA regulations regarding cylinders.

3.12 FIRST AID

Refrigeration and air-conditioning workers are advised to enroll in an approved first-aid course. Some vocational programs and technical colleges offer first aid as an elective course. Be sure to talk to your adviser about taking a first-aid course. Prompt and correct treatment of injuries not only reduces pain but could also save lives. A classification of accidents that occur to HVACR personnel, related to the hazards described, include the following:

1. Injuries due to mechanical causes
2. Injuries due to electrical shocks
3. Injuries due to high pressure
4. Injuries due to burns and scalds
5. Injuries due to explosions
6. Injuries due to breathing toxic gases
7. Injuries due to negligence when working with electricity (Always pay strict attention to the work, and never allow any horseplay, as this could cause you or someone you are with to receive serious injury or die.)
8. Heat exhaustion or heat stress

3.13 ELECTRICITY SAFETY

All possible precautions must be practiced to prevent electrical shock—that is, current passing through the body. Very few realize the damage that can be done by even a small amount of current.

The following information applies to low-voltage circuits where current is measured in milliamps (mA). One amp (A) is equal to 1,000 mA.

The illustration in Figure 3-14 indicates the effect on the body when various amounts of current pass through the body at 100 mA or less.

Noncontact voltage (NCV) testers should be a standard tool for all HVACR service technicians. Some digital multimeters incorporate an NCV feature.

Electrical Safety Rules

1. Check all circuits for voltage before doing any service work. Tag and lock out all electrical disconnects when working on live circuits.
2. Stand on dry, nonconductive surfaces when working on live circuits.
3. Work on live circuits only when absolutely necessary.
4. Use only properly insulated tools to work on electrical circuits.
5. Never bypass an electrical protective device.
6. Properly fuse all electrical lines.
7. Properly insulate all electrical wiring.
8. Use ground fault circuit interrupters whenever using power tools.

3.14 REFRIGERATION SAFETY

The hazards associated with refrigeration service are principally associated with the proper use of refrigerants and their storage in closed containers and systems. A large improvement was made when the HVAC industry started using the so-called safe refrigerants (Class I, or fluorocarbons),

Figure 3-14 Amperage rating of electric current creating various shock effects from 1 mA up to 100 mA. (© WorkSafeBC. Used with permission from Working Safely Around Electricity.)

which were nontoxic and nonflammable. Dangers now relate to the use of pressurized gas or liquid and the fact that these chemicals, when released accidentally, can replace oxygen in a confined space without sensory detection.

CAUTION

From time to time it may be necessary to warm a refrigerant cylinder so that system charging can proceed. Never heat a refrigerant cylinder with an open flame. This could cause two problems: the open flame could cause a rapid rise in cylinder pressure above the rupture point of the cylinder, and the high heat can cause the refrigerant to decompose. Three safe ways of warming cylinders are to place the cylinder in a warm bath of water, place the cylinder in the warm discharge air from the condenser fan, or wrap an electrical cylinder heater around the cylinder (Figure 3-15).

Used Refrigerants and Refrigerant Oils

The EPA classifies all used refrigerants and used refrigerant oils as hazardous waste that must be disposed of properly. They must be taken to a state or locally approved recycler that specializes in used refrigerants and used refrigerant oils. Often these recyclers have local or state certifications that you can obtain copies of for your records. It is a good idea to keep accurate and complete records showing how and where all of the used refrigerant and used oil you collect was disposed. Although these records are not required

Figure 3-15 An electrical cylinder heater can be used to safely raise cylinder temperature. (Courtesy of Airserco Manufacturing Company)

by the EPA, you may be asked to prove that you are complying with all disposal requirements. Having good documentation can help show the EPA, if your records are audited, that you are complying with all the laws and regulations regarding disposal of hazardous waste.

Used refrigerant oil and used automotive oils are not compatible and cannot be mixed for disposal. That is why used refrigerant oil cannot be disposed of at an automotive oil recycler unless they have special containers just for used refrigerant oil.

CAUTION

It is illegal to sell any used CFC (chlorofluorocarbon) or HCFC (hydrochlorofluorocarbon) refrigerants that have not been reclaimed by an EPA-certified reclaimer.

Handling Refrigerant Cylinders

1. Do not fill a cylinder with liquid refrigerant to more than 80 percent of its volume. Heat can expand the liquid enough so that it fills the cylinder. Once that occurs, the cylinder will rupture. Space must be available inside the cylinder for proper expansion of the liquid to take place. In recovering refrigerants, this is particularly important. Special cylinders with an automatic volume-limiting device have been designed for recovery.
2. In using a cylinder or transporting it, the cylinder must be secured with a chain or a rope in an upright position. Do not drop a cylinder.

3. Mixing refrigerants is dangerous. Cylinders are color coded to help identify each refrigerant. Each system has an identifying label. Do not mix refrigerants. Maintain the identification system.
4. Never apply a torch to a system containing refrigerant. If heat is needed to vaporize refrigerant, use hot water at a temperature not to exceed 125°F (52°C).
5. Do not refill disposable refrigerant cylinders.
6. Replace the cylinder cap when not using a cylinder. The cap protects the valve. Do not lift or carry a cylinder by the valve.

SERVICE TIP

Most refrigerant cylinders come in cardboard boxes. These boxes contain important safety information. Some industrial plant safety officers will require that you maintain these cardboard containers with the safety material listed whenever you are working on their job site.

Refrigerant System Safety

1. Never use oxygen or acetylene to pressurize a system, because an explosion can occur. Use dry nitrogen or carbon dioxide from a tank properly fitted with a pressure regulator.
2. When isolating a section of piping or component of a system, exercise caution to prevent damage and potential hazard from liquid expansion.
3. Always charge refrigerant vapor into the low side of the system. Liquid refrigerant entering the compressor could damage the compressor or cause it to burst.
4. Never service a refrigeration system where an open flame is present. The flame must be enclosed and vented outdoors. If a fluorocarbon refrigerant comes in contact with intense heat, it can produce poisonous phosgene gas.

3.15 PRESSURE VESSEL SAFETY

Pressure vessels pose three major hazards if they rupture: The blast from the sudden explosion can cause serious internal injury. The pressurized liquid can cause severe burns. And fragments of metal thrown from the exploding vessel can cause lacerations and punctures. All pressure vessels pose some degree of hazard to individuals working in the area, so they must be inspected for flaws that might weaken their integrity.

There are a number of pressure vessels used in the HVACR field. These include accumulators, receivers, refrigerant cylinders, low-pressure boilers, high-pressure boilers, and hot water tanks. Both low- and high-pressure boilers and many commercial hot-water tanks are required to be inspected periodically. The type and frequency of inspection varies depending on the type of pressure vessel. There must be a placard displayed on or near the pressure vessel showing when it was inspected and giving the date when it needs to be reinspected.

Some pressure vessels, such as accumulators and receivers, may not have to be inspected. It is, however, a good idea to inspect them for rust, corrosion, cracks, and

other signs of physical damage that may render them unfit for service.

Refillable refrigerant cylinders, such as those that are used for refrigerant recovery, must be inspected every five years. The inspection date must be stamped on the top of the cylinder. Cylinders that have not been inspected within five years cannot be used.

3.16 DRIVING SAFETY

A good driving record is essential for any job that requires that you drive. Almost all HVACR work requires that you do some driving as part of your job. Outside service technicians may spend much of their day driving from one job to another.

Your driving record will affect the insurance rate the company must pay. In some cases a very bad driving record could make you unemployable due to the high insurance rates your employer would have to pay so you could drive their service vans.

You cannot speed or drive recklessly or aggressively in a service vehicle. To do so could result in bad public relations for your company. In addition, with almost everyone having a cell phone, the chance that someone would call your boss and report your actions is very high. Even worse would be if they use their cell phone to take a picture or video of your driving and send that to your boss. You might be the best technician the company has, but you can still lose your job because of your actions behind the service vehicle's wheel.

If you are involved in an accident, make sure to get all of the other driver's information. You should also get any contact information from anyone who may have witnessed the accident.

TECH TIP

Carrying a disposable camera in the vehicle glove box will let you take photos of the accident and of any cars in the area. Make sure to get photos of the license plates of potential witnesses to the accident. A few photos taken shortly after the accident can help you prove your side of the story, if necessary.

3.17 STEPS TO BE FOLLOWED IN CASE OF AN ACCIDENT

1. If the injuries appear to be serious, call 911 or your local emergency number.
2. First aid should be administered, if needed, only by those qualified to do so.
3. All accidents, injuries, and illnesses should be reported to your boss or supervisor no matter how minor the injuries may seem.

4. An accident report form should be filled out and turned in to your company office.
5. An investigation of the accident may be done to determine the cause of the accident.
6. Clean up the area before resuming work.

UNIT 3—SUMMARY

Schools provide a safe environment in which to *learn*, but it is your responsibility to always *work* safely. You must follow all of the rules and standards, because electricity, compressed gases, and other potential hazards do not know you are a student; you may not get to make a safety mistake more than once.

If you have not been trained on the safe operation of any tool, equipment, or device, do not attempt to use it.

Safe working habits can last a lifetime. Start now and learn everything you can to make your HVACR career a long and safe one.

UNIT 3—REVIEW QUESTIONS

1. What causes accidents, and how they can be eliminated on the job site?
2. What is PPE?
3. Discuss ladder safety.
4. Discuss scaffold safety.
5. What is the difference between fall-prevention equipment and fall-arresting equipment?
6. Describe how cold can cause a burn on skin.
7. List harmful respiratory substances.
8. Explain some of the dangers of refrigerants.
9. Explain what material appears on every Material Safety Data Sheets (MSDS).
10. Discuss how to safely use hand tools.
11. Discuss how to safely use power tools.
12. Discuss how to practice safety in the shop.
13. List four types of fire extinguishers.
14. Tell how to safely lift heavy objects.
15. Discuss safe welding cylinder practices.
16. Discuss electrical safety rules.
17. When a refrigerant cylinder needs to be warmed, how should it be done?

UNIT 4

Hand and Power Tools

OBJECTIVES

After completing this unit, you will be able to:

1. identify the major tools used in HVACR work.
2. describe how the major HVACR tools are used.

3. explain the safety procedures required for using different types of tools.
4. demonstrate how to care for tools.

4.1 INTRODUCTION

The care and use of tools are important considerations for the technician. The customer often judges a technician on the appearance of his tools. They often assume that a technician that has a dirty, poorly maintained, and disorderly tool bag will provide the same type of service. To a large extent this is true, because it is harder to work with poorly maintained tools, and a tool bag that is not well organized makes it take longer to locate the tools for the job. The way you maintain your tools reflects on your quality of workmanship. In addition, injury can frequently be traced to a lack of, or improper use of, hand tools. Clean, sharp tools are better to work with and safer to use. This unit describes the purpose and use of some of the most basic hand and power tools needed by the HVACR technician. Specialty instruments, electrical meters, gauge manifold sets, and tubing/piping tools are described in other follow-on units of the text.

4.2 TOOL KITS

Tool manufacturers package tools in kits (see Figure 4-1), and tool kits are available for most types of HVACR jobs. They are easier to store and have greater convenience than loose tools. Kits come in many sizes and price ranges. A complete kit includes wrenches, hex keys, screwdrivers, nut drivers, pliers, knives and cutters, measurement tools,

electrical repair tools, flaring/swaging/cutting tools, a multi-meter, a gauge manifold set, and a clamp-on ammeter.

The basic tool kit should include varying sizes of combination, adjustable, refrigeration service, and hex key (Allen) wrenches. There should be an assortment of slotted and Phillips screwdrivers along with nut drivers. Pliers are an essential tool for the technician, and different types—such as lineman's side cutting pliers, needle-nose(long-nose)pliers, diagonalcuttingpliers, tongue-and-groove pliers, slip-joint pliers, and multipurpose wire strippers—will be necessary.

Specialty tools can be added to the tool kit over time, and because all tools are expensive, they should be maintained properly. It is recommended that you keep your tool kit locked and placed in a secure location when not in use. Keep an inventory list so that you can check it after each job. Good quality tools will provide for many years of service if you take care of them.

4.3 TOOL CARE AND USE

Keep tools in a safe place. Never carry tools in your pockets or leave them lying around. A ripped car seat caused by a screwdriver left in your back pocket spoils a good day on the job. A round screwdriver lying on the ground is an accident waiting to happen because someone will step on it, slip, and fall. Other accidents can occur from using damaged tools. Pieces of metal will fly from a chisel that has a mushroomed head when struck with a hammer (Figure 4-2). That is why safety glasses must be worn whenever using hammers and chisels. Don't keep damaged tools. Throw them away and make sure to dispose of them properly.

You not only need to have the right tool, but it must be used properly. As an example, pliers are not made for tightening or loosening nuts (Figure 4-3). This will round off the corners of the nut and make it increasingly more difficult to

Figure 4-1 Prepackaged tool kit.

Figure 4-2 Chisel with mushroomed end.

Figure 4-3 Pliers are not made for tightening or loosening nuts.

remove. Use the proper wrench or socket that fits even if it takes a few extra minutes to find it in your toolbox.

TECH TIP

Air-conditioning and refrigeration hand tools do not get as dirty as most mechanics' tools will. However, it is a good idea to wipe them down with a clean, dry rag after each use. In addition, from time to time they should be rubbed with a lightly oiled cloth to protect them from rusting.

4.4 SCREWDRIVERS

Screwdrivers are commonly required for almost every type of HVACR work. These are available in many different shapes, sizes, and materials. They are used for driving or removing screws or bolts with slotted, recessed, or special heads. Never use a screwdriver for prying, punching, chiseling, scoring, or scraping, and they should never be pounded with a hammer! Do not use a screwdriver near a live electrical wire or circuit.

Screwdrivers have a handle connected to a blade (sometimes called a shank) by a ferrule as shown in Figure 4-4. Flat and Phillips tips are the most common types of screwdrivers (Figure 4-5). A flat-tip screwdriver is usually called a flat blade. However, the length of the blade from the handle to the tip may be round or square. A heavy-duty screwdriver may have a square blade so that a wrench can be used to turn it (Figure 4-6). A screwdriver should be chosen to match the head of the screw (Figure 4-7). It is important to have a tight fit between the screw and screwdriver

Figure 4-4 Parts of a screwdriver.

Figure 4-5 Screwdrivers come in a variety of sizes and lengths.

Figure 4-6 Using a wrench to assist in turning a square blade screwdriver.

Figure 4-7 The screwdriver should match the head of the screw.

Figure 4-8 Cross-point Phillips screwdriver tip.

tip, otherwise it can be possible to strip the screw slot. Phillips screwdrivers are designed with a tip that is shaped like a cross. Therefore, this type is also referred to as cross-tip (blunt at the tip) and cross-point (sharp point at the tip) screwdriver (Figure 4-8).

Do not hold the work in one hand while using the screwdriver with the other. If the screwdriver slips out of the slot, it may gash your hand. Keep the screwdriver in line with the screw and use your other hand to keep the blade steady (Figure 4-9).

Specialty Screwdrivers

Six-way screwdrivers have two sizes of flat tips and two sizes of Phillips tips as well as two sizes of nut drivers (Figure 4-10). These are very popular for HVACR service work. Some screwdrivers have very short blades and are stubby to allow you to work in a tight area where a regular screwdriver will not fit. Offset screwdrivers can also be used in these hard-to-reach areas (Figure 4-11).

Screwdrivers can have thin blades and tips that are convenient for turning small screws like the types that are commonly found securing electrical wires on control circuits and thermostats (Figure 4-12). Other screwdrivers, such as Torx, Spline Drive, and Bristol types, have different blade tip shapes (Figure 4-13). These are designed so that

Figure 4-14 Some specialty blade tips provide greater contact and less chance for slippage.

there is less chance for the screwdriver to slip out of the slot (Figure 4-14).

Nut Drivers

The nut driver is useful in tightening or removing hex-head sheet-metal screws or machine screws that hold equipment panels in place or fasten control box covers. They look like screwdrivers with a handle, ferrule, and blade

(Figure 4-15). However they differ from screwdrivers in that the tip has a drive socket to fit over the nut or screw hex head (Figure 4-16). Some nut drivers have magnetic ends that hold the screw head in the nut-driver end.

4.5 PLIERS FOR MECHANICAL WORK

There are a number of different types of pliers used in HVACR work. Slip-joint, tongue-and-groove, and locking pliers are primarily used for mechanical work.

Slip-Joint Pliers

Slip-joint pliers have serrated (grooved) jaws and are handy for general use and for holding hot parts or grabbing something that is being removed (Figure 4-17). The pivot is used to adjust the jaw opening to handle large or small objects (Figure 4-18).

Tongue-and-Groove Pliers

Tongue-and-groove pliers (multitrack) are used like slip-joint pliers except they open wider to hold or grab larger items, such as pipe (Figure 4-19). They come in different sizes with various jaw configurations, such as straight jaw, smooth jaw, and narrow jaw.

Figure 4-17 Using pliers to grab a cotter pin.

Figure 4-18 Adjusting slip-joint pliers to make them smaller or larger.

Figure 4-19 Tongue-and-groove pliers: (a) adjusted to minimum size; (b) adjusted to maximum size; (c) adjusted to hold pipe.

Locking, or Vise-Grip, Pliers

Locking, or vise-grip, pliers also come in different sizes with different jaw styles (Figure 4-20). They clamp and lock to hold parts securely. Their locking-clamp action is beneficial because once the pliers are clamped in place you can let go of them, which frees your hand (Figure 4-21).

CAUTION

Do not use pliers to tighten or loosen brass fittings. No matter how delicately you use pliers on these fittings, the fitting surface will be damaged. This damage can prevent the next technician from using the proper wrench on the damaged fitting.

4.6 PLIERS FOR ELECTRICAL WORK

Diagonal cutters, needle-nose, and lineman's pliers are primarily used for electrical work (Figure 4-22). These types of pliers can be damaged at the cutting surface if they are used for cutting materials other than copper wire. Cutting a hard material such as a nail can put a notch in the cutter and/or dull the cutting edge. In either case, damaging the cutter will render your pliers useless for HVACR work. If you have to cut nails, use a hacksaw or an old pair of pliers, not your good electrical pliers.

Figure 4-20 Locking pliers.

Figure 4-21 (a) Locking pliers before clamping; (b) locking pliers clamped.

Figure 4-22 (a) Wire cutters; (b) needle-nose pliers; (c) lineman's pliers.

Lineman's Side-Cutting Pliers

Lineman's side-cutting pliers have serrated jaws, a rod-gripping section, side cutters, and a wire cropper. The flat jaws are used to bend sheet metal and twist electrical wire (Figure 4-23). The rod-gripping section is used to hold and

Figure 4-23 Lineman's pliers: (a) preparing electrical wires; (b) twisting electrical wires.

Figure 4-24 Cutting electrical wires with lineman’s side-cutting pliers.

bend small rods. The side cutters permit sharp flush cuts on electrical wire (Figure 4-24). A pair of croppers located above the pivot is used to shear larger wire.

Diagonal Cutting Pliers

The jaws on diagonal cutting pliers are offset by about 15 degrees. They are not used to hold or grip objects. Diagonal cutting pliers are used for making flush cuts on small, light materials such as wire, cotter pins, and similar objects (Figure 4-25).

Multipurpose Wire Strippers

Wire strippers are used to strip insulation from electrical wires (Figure 4-26). When closed around the wire, only the insulation is cut, leaving the wire itself intact (Figure 4-27). They can also be used to cut the wire (Figure 4-28).

Figure 4-28 Cutting stripped electrical wire to length.

4.7 WRENCHES

The term *wrench* is used to describe tools that grip and turn threaded parts such as nuts, bolts, valves, and pipes. Some wrenches are adjustable, so they will fit a range of sizes of nuts, bolts, or pipes, as shown in Figure 4-29. Other wrenches have fixed sizes and come as sets to fit common sizes, as shown in Figure 4-30. Some wrenches are specifically designed for HVACR jobs, such as the service valve wrench as shown in Figure 4-31.

Figure 4-29 Adjustable wrenches come in a variety of sizes.

Figure 4-30 Combination wrenches: one end is open and the other end is boxed.

Figure 4-31 Refrigerant service valve wrenches have square openings.

Service Valve Wrenches

Service valves on some compressors and condensers are $\frac{1}{4}$ -in (6 mm) square stems and require a special service valve wrench. Service valve wrenches come in several styles and shapes. Some service valve wrenches use a ratchet mechanism. The ratchet may be fixed in one direction so the wrench has to be removed and turned over to change directions. Other service valve wrenches may have a lever for reversing the rotation of the wrench as required for either opening or closing the valve (Figure 4-32). Reversible-ratchet service valve wrenches can have up to four fixed sizes of square openings, ranging from $\frac{3}{16}$ in, $\frac{1}{4}$ in, $\frac{5}{16}$ in, and $\frac{3}{8}$ in (4 mm, 6 mm, 8 mm, and 9 mm) (Figure 4-33). These service valve wrenches look similar to the ratchet wrenches used by auto mechanics, but those wrenches have hex openings to fit the heads of standard nuts and bolts.

The handles on service valve wrenches can be flat or offset. The offset gives your hand a little more clearance in tight places (Figure 4-34). Most HVACR technicians carry

Figure 4-32 Ratchet service valve wrench.

Figure 4-33 Some ratcheting refrigerant service valve wrenches provide four different-sized openings by having two different sizes on each end: (a) $\frac{1}{4}$ and $\frac{3}{8}$ in sizes; (b) $\frac{3}{16}$ and $\frac{5}{16}$ in sizes.

Figure 4-34 Refrigerant service valve wrenches are available with offsets to provide some hand clearance when using the wrench.

more than one type of service valve wrench to meet the varying job needs.

Box-End, Open-End, Combination, and Flare-Nut Wrenches

Box-end wrenches completely encircle the bolt head or nut and are strong and are resistant to slipping. They are ideal for working on long-shaft bolts (Figure 4-35) or tight spaces where a socket would not easily fit (Figure 4-36). Another

Figure 4-35 Offset box-end wrench.

Figure 4-36 A box wrench is used because the compressor process tube would interfere with a socket wrench.

(a)

(b)

Figure 4-37 (a) Open-end wrench with 15-degree offset openings, both ends; (b) combination box open-end wrenches.

very common wrench, the open-end wrench, is appropriately named because it does not completely encircle the bolt head or nut but instead is open (Figure 4-37a). Because open-end wrenches do not need to fit over the top of the bolt head or nut, they are excellent for work where access is limited or the end of the bolt cannot be reached. Combination box open-end wrenches have one end open and one box end (Figure 4-37b). All of these types of wrenches may have straight or offset handles.

The flare-nut wrench is a special variation of the box wrench in that the heads are slotted to allow the wrench to slip over the tubing and then onto a flare nut (Figure 4-38).

Figure 4-38 Tubing wrenches.

Figure 4-39 Pulling the wrench provides for better control.

Figure 4-40 Push the wrench with your palm to protect your knuckles.

SERVICE TIP

Wrenches should always fit securely over the bolt head or nut before force is applied. If the wrench slips, you will jam your fingers. It is always best to try to pull rather than push on a wrench (Figure 4-39). You will have more control and will be less likely to jam your fingers or rap your knuckles. If you must push, then use an open palm so you're your fingers do not become jammed between the wrench and the work as the wrench begins to turn (Figure 4-40).

Adjustable Wrenches

Crescent Tool Company was the first to introduce the adjustable wrench (Figure 4-41). The adjusting wheel permits fitting the flat to any size object within the maximum and minimum opening. Always use this type of wrench in a manner such that the force is in a down or counter-clockwise direction with the movable jaw on the bottom when loosening a bolt. This keeps the force against the fixed head so the wrench is less likely to suddenly slip and injure you (Figure 4-42). Adjustable wrenches are available in sizes from 4 in to 12 in (102 mm to 305 mm).

Figure 4-41 Adjustable wrench.

Figure 4-42 Always pull an adjustable wrench so that the force is correctly applied to the movable jaw and the wrench is less likely to slip.

Figure 4-43 (a) Standard size Allen wrenches; (b) metric Allen wrenches.

Allen Wrenches

Allen wrenches often come in sets. Some are short, referred to as standard Allen wrenches, and others are long. The sets should be marked as to whether they are standard or metric sizes (Figure 4-43). The hexagonal shaft of the Allen wrench fits into the Allen screw typically used on fan pulleys, fan blade hubs, and other components. Allen wrenches are also available in a pocket set (Figure 4-44). There are some Allen wrenches that have ball ends that allow the wrench to be at an angle and still go inside the set screw. Another specialty Allen wrench is the one used with the refrigerant ratchet wrench to access the service valves on most condensing units (Figure 4-45).

Figure 4-44 Pocket Allen wrench set.

Figure 4-45 Allen wrench designed to fit in service ratchet wrench: (a) part of Allen wrench for accessing most suction-line service valves; (b) section of Allen wrench for accessing liquid-line service valves.

SERVICE TIP

Allen wrenches are often used to loosen and tighten pulley set screws. These screws are often very tight and difficult to remove. Make certain that the Allen wrench tip is fully inserted to the complete depth in the set screw before trying to tighten it or loosen it (Figure 4-46). Failure to insert the Allen wrench to its full depth can result in damage to the wrench or to the set screw.

Figure 4-46 (a) Allen wrench and set screw; (b) the Allen wrench must be fully inserted into the set screw before turning.

4.8 SOCKET WRENCHES

Socket wrenches are made to slip over the heads of bolts and nuts (Figure 4-47). They are made of tool steel and usually come as sets in either standard or metric sizes.

Although standard sockets are available in sizes ranging from $\frac{1}{16}$ in up to several inches in size, the most common set would have sockets sizes starting with $\frac{1}{4}$ in up to 1 in by $\frac{1}{8}$ in or $\frac{1}{16}$ in increments (Figure 4-48). Common metric socket sets range from 6 mm to 25 mm.

Both standard and metric socket sets for standard hexagonal nuts or bolts can be either six point or twelve point (Figure 4-49). The six-point sockets are stronger, but the twelve-point sockets allow easier alignment and shorter swing for tight locations. Swivel sockets and universal joints are also useful for reaching bolts that are hard to get at (Figure 4-50).

Socket Handles

A number of designs of socket wrench handles, referred to as socket handles, are available. Ratchet socket wrench

handles are the most common type of handles because they can be used to quickly loosen and remove or install and tighten nuts and bolts. Some ratchets have swivel heads that are helpful for working in tight places (Figure 4-51). There are two dimensions used to refer to socket handles: length and size. The length refers to the distance from the tip of the handle to the head. The size refers to the dimension of the square shank that fits into the socket. The three common sizes for this shank are $\frac{1}{8}$ in, $\frac{1}{4}$ in, and $\frac{3}{8}$ in. Adapters are available to allow larger or smaller shank sizes to be used with different sized socket sets (Figure 4-52).

Breaker-bar socket wrench handles are used when a great deal of force is required to remove a stuck or stubborn bolt or nut. They are designed to take significantly more force than ratchets, but never use a cheater bar or pipe to extend the handle for more leverage, because this could damage the wrench.

Figure 4-50 (a) Universal joint; (b) the universal joint allows the extension to be used at a slight angle.

Figure 4-51 Swivel-head ratchet handle.

Figure 4-52 Socket wrench adaptors are available that permit more than one size socket to be used with different-sized wrenches.

SERVICE TIP

From time to time it is necessary to use an extension on a socket to reach way down inside a piece of equipment to remove or install a bolt or a nut. For example, the mounting bolts on a compressor inside of a residential condensing unit may require a foot-long extension or more. A problem can exist when you try to reach back in this tight space to reinstall the bolts. There may not be room for your hand and the wrench. However, if you use a small piece of paper, possibly folded one or two times, and place it over the head of the bolt before pushing the head into the socket, this can be used to hold the bolt or nut in the socket as it is lowered down into the confined space. This trick can save a lot of aggravation. Some manufacturers do provide small magnets that can be placed in the sockets, which can serve the same purpose. However, the paper trick works when you do not have the magnets.

Figure 4-53 Torque wrench.

4.9 TORQUE WRENCHES

Torque wrenches have a gauge to measure the force being applied. The dial on the wrench indicates the amount of pressure being applied to turn the bolt (Figure 4-53). Torque is a twisting action. Torque is measured in inch pounds (in lb), foot pounds (ft lb), or newton meters (Nm) as applied to the wrench handle. Making sure the same force is used on nuts and bolts is important, especially when tightening the heads on compressors. Uneven tightening can result in the head being warped or bolts being stripped or broken. Either case can render the compressor unusable or more expensive to repair. Typical specifications will give both the torque and the tightening sequence (Figure 4-54). A good torque practice is to first apply only a light torque to each bolt in the recommended sequence. Then repeat the tightening sequence and each time increase the torque slightly until the required torque is reached.

Figure 4-54 Typical head-torquing sequence—check with the manufacturer for specific torquing sequences and torque specifications.

Figure 4-55 Pipe wrench.

4.10 PIPE WRENCHES

The pipe wrench is used in refrigeration installation and service work to assemble or disassemble threaded pipe (Figure 4-55). At least two sizes are recommended. An 8 in (203 mm) wrench can handle up to 1 in (25 mm) diameter pipe, and a 14 in (356 mm) size can handle up to 2 in (50 mm) diameter pipe (Figure 4-56). Some have replaceable jaw inserts to extend the life of the tool. The chain wrench is another form of adjustable pipe wrench. This wrench can make work easier in a confined area or on round, square, or irregular shapes.

4.11 HAMMERS, PUNCHES, AND CHISELS

There are a wide variety of hammers and mallets used in the HVACR trade. Some of the more common hammers used are ball-peen hammers, sheet-metal hammers, claw

Figure 4-56 10-in, 14-in, and 24-in pipe wrenches.

Figure 4-57 The proper way to hold a hammer is near the end of the handle.

hammers, mallets, and sledge hammers. The proper way to hold any hammer is near the end of the handle (Figure 4-57). The wrist and arm motion that you use will depend on how hard you must strike the object. A light tap is almost entirely wrist motion. Heavy blows come from the wrist, forearm, and shoulder.

Ball-Peen Hammer

The ball-peen hammer is sometimes referred to as a machinist's hammer. These hammers are used for some sheet-metal work (Figure 4-58) and can be used when striking metal surfaces.

Sheet-Metal Hammers

The flat end of a sheet-metal hammer is used to close Pittsburgh joints and drive in a drive cleat, bend the end of a drive cleat, and other similar tasks. The tapered end is sometimes used to open up the folded edge of a drive cleat or to unbend a seam (Figure 4-59). These hammers can be used to strike metal surfaces.

Figure 4-58 Ball-peen hammer. (Courtesy of Terra Community College HVAC Program, Fremont, Ohio)

Figure 4-59 Sheet-metal hammer. (Courtesy of Terra Community College HVAC Program, Fremont, Ohio)

Claw Hammer

The claw hammer is commonly used in carpentry work and should never be used to strike hard metal surfaces. The hammer may be damaged or the face may be chipped if used to strike metal. The claws are used for pulling nails (Figure 4-60).

Mallets

Mallets are generally larger in diameter than hammers and may or may not have hard faces. Some mallets are made of wood, rawhide, plastic, rubber, or other similar material (Figure 4-61). Mallets are used when it is important that the surface not be damaged, such as driving shafts, tapping large pieces of equipment into place, or other similar tasks.

Sledge Hammers

Sledge hammers may have long or short handles and are used when heavier strikes are required to dislodge stuck large motor shafts, break up concrete, and so on (Figure 4-62).

Figure 4-60 Claw hammer. (Courtesy of Terra Community College HVAC Program, Fremont, Ohio)

Figure 4-61 Wood and rubber mallet. (Courtesy of Terra Community College HVAC Program, Fremont, Ohio)

Figure 4-62 Sledge hammer. (Courtesy of Terra Community College HVAC Program, Fremont, Ohio)

Chisels and Punches

Chisels and punches are usually struck with a hammer. Strike the tool squarely and on center to prevent the hammer from glancing off. There are a large variety of chisels. Machinist's chisels are designed to cut and shape cold metal. The cape chisel is used for cutting keyways or slots in metal. The rivet buster is used for cutting rivets. The end of the chisel that is struck by the hammer may become mushroomed over time. When this happens the chisel should be replaced because as the end mushrooms, pieces of metal may fly off when the chisel is struck by the hammer.

Punches are used to mark metal, drive pins, and align holes. Drift punches are generally used to remove shafts, pins, and rivets and to align small parts. An alignment punch helps to line up mating parts for assembly. The drive punch has a flat tip for driving nails or pins, while the prick punch has a pointed tip to mark metal (Figure 4-63).

Figure 4-63 Handheld drive and prick punches.

4.12 HACKSAWS AND FILES

The hacksaw is used to cut metal. There are two types of blades: hard and flexible. The blade teeth are designed to cut in one direction only, and the blade will be marked to show which end is connected near the saw handle (Figure 4-64). Cutting is accomplished as you push the saw, not when you pull back (Figure 4-65). Some hacksaws are designed for tight spaces and hold the blade differently than conventional hacksaws (Figure 4-66).

Files come in several shapes: flat or rectangular, round, half round, triangular, square, and so on. In refrigeration work, the common flat file and the half round are used in preparing tubing for soldering by squaring the end or for removing burrs.

Figure 4-64 Install a hacksaw blade with the teeth pointed in the proper direction.

Figure 4-65 The hacksaw will cut as you push.

Figure 4-66 Smaller hacksaws can cut in areas where larger hacksaws cannot reach.

Figure 4-67 (a) This single-cut file will require its handle to be attached before safe use; (b) This cross-cut file has its handle formed as part of the file.

Files can be either single cut or cross cut (Figure 4-67). A single-cut file is used for finishing a surface, such as in preparing copper pipe for soldering. A cross-cut file is coarser and would be used where deeper and faster metal removal is needed. A rasp is an extremely coarse cross-cut file intended for very rough work.

4.13 VISES AND CLAMPS

A machinist's vise (Figure 4-68) can be very useful when mounted in a service van. The pipe vise on a tripod stand (Figure 4-69) is a requirement both in the field and in the shop to hold tubing or pipe while cutting or threading opera-

tions are taking place. C-clamps are used to hold work that cannot be held in a vise or that has to be held for extended periods (Figure 4-70). They are available in a variety of sizes. The threads and the swivel should be periodically cleaned with a rag and lubricated with a light coat of oil.

(a)

(b)

Figure 4-70 (a) C-clamps; (b) C-clamp holding bonnet of valve.

CAUTION

When holding copper or other soft metal, be sure that the jaws are soft so as not to mar the surface and that the clamping pressure does not squeeze the tubing out of round.

4.14 KNIVES AND SCRAPERS

Knives are universal tools that have many functions. There will always be times when you need to cut twine or open a cardboard box. A handy tool is the combination blade and razor knife (Figure 4-71). The razor held at one end of the knife is replaceable. When using a knife, always cut away from your body, not toward it. When not in use, the knife should be folded or put in a sheath. Never carry an open knife in your pocket.

Flat-blade scrapers or putty knives are useful for removing gaskets and cleaning flange faces (Figure 4-72). Be careful when scraping a surface not to slip. A sharp scraper edge is less likely to slip. Be careful not to scratch the surface of a flange face when scraping off an old gasket. When a scraper is not in use, it is a good practice to coat the blade with a film of light oil to prevent it from rusting.

4.15 TAPS AND DIES

Taps and dies are used to cut threads in metal, plastics, or hard rubber. Taps are for the internal (female) threads, and dies are for the external (male) threads (Figure 4-73). They are made of hardened steel and must be placed squarely over the stock or in the hole to prevent cross-threading. Rethreading dies (thread chasers) often come in handy to

Figure 4-71 Combination razor and blade folding knife.

Figure 4-72 (a) Flat-blade scraper; (b) side view.

Figure 4-73 Tap and die.

restore threads that are rusty or have been nicked or damaged. When using a thread chaser, make sure the tool turns on hand tight to start to prevent cross-threading. Once taps and dies become dull they cannot be resharpened and therefore must be replaced.

4.16 POWER TOOLS

Safety

Never operate any power equipment unless you are completely familiar with its control and features. Inspect all portable power tools before using them. See that they are clean and in good condition with no frayed or cut wires. Make sure there is plenty of light in the work area. It is important to ensure that your tools are properly grounded. This means that the plug on the tool should have three prongs. Always make sure the tool is in the OFF position before connecting it to a power source.

Many power tools have built-in safety features. Take, for example, a battery-powered staple gun. You would not want the staples to accidentally fly out in every direction if the trigger were accidentally pressed. Most powered staple guns have a safety switch that will not allow the gun to operate unless it is held firmly against the work (Figure 4-74).

Figure 4-74 The power stapler safety switch must be depressed with stapler held in place on the work before the stapler will operate.

SAFETY TIP

Some portable electric tools provide for double-insulated casings and do not need to be grounded. This type of tool may only have a two-prong plug rather than three. If a tool plug has three prongs, never use an adapter to make it fit a two-prong receptacle unless the adapter is properly grounded.

Drills

Drills are frequently used to both drill holes and drive screws. Cordless drills with interchangeable batteries are ideal for HVACR work (Figure 4-75). A useful drill should have a variable speed control plus a reversing switch to back out stuck bits. Bit selection will depend, of course, on the nature of the material, but at a minimum, a set of high-speed alloy steel bits for metal is a must (Figure 4-76). Such bits can also be used for drilling wood and plastic. However, masonry bits and wood-boring bits may be added for more intensive job requirements. Drill guides are useful tools to quickly measure the diameter of a drill bit (Figure 4-77). In addition to drilling

holes, battery-operated drills are commonly used for driving screws (Figure 4-78). There are various types of screwdriving attachments to suit many particular jobs (Figure 4-79).

For more than occasional drilling of concrete or masonry for anchors and shields, nothing beats a rugged rotary hammer drill with the proper carbide masonry bits. The savings in time can quickly pay for the tool.

TECH TIP

Power converters are devices that plug into a vehicle's 12V outlet. They convert 12V DC to 120V AC. Power converters are excellent additions to your service vehicle tools because they allow standard portable drill battery chargers to be used during the workday to keep your spare battery charged.

Bench and Hand Grinders

Bench grinders are used to sharpen tools, dress screwdrivers, and shape and smooth metal stock. A bench grinder will have two different types of grinding wheels: one is fine and the other is coarse (Figure 4-80). Aluminum, brass, and copper should not be used on the bench grinder unless the grinding stone is made for those materials. Bench grinders are equipped with Plexiglas safety shields and tool rests. The space between the grinding wheel and the tool rest is approximately 1/16 in, but never over 1/8 in (Figure 4-81). Always be sure that the wheel guards, tool rests, and shields are properly positioned before applying power. Stand to the side of the grinder when turning it on, and allow the machine to run for one minute before

Figure 4-80 Bench grinder.

Figure 4-81 Always ensure the proper spacing between the grinding wheel and the tool rest.

engaging the wheel with work. Never use a glazed, worn, or uneven wheel.

Handheld grinders must be firmly held with both hands (Figure 4-82). For added safety, they are equipped with a spring-loaded switch that cuts off the power when the hand grip is released. Always use a vise or clamp to hold the work, and never hold the object to grind by hand. Eye protection must always be worn when using grinders.

Figure 4-82 Hold a hand grinder firmly with both hands.

Figure 4-83 The handy jigsaw can cut wood, plastic, and light metal.

Power Saws

There are a variety of different types of portable power saws. The most familiar may be the circular saw, which is good for new construction when cutting studs and other framing members. Also used in construction and renovation is the reciprocating saw with a single straight blade, which can be used to saw out holes in walls and remove existing framework. The portable electric band saw can be used for sawing PVC tubing and light-duty pipe. The handy jigsaw can be used to cut wood, plastic, and metal, depending on the type of blade inserted (Figure 4-83). Its small size and scrolling features for cutting irregular shapes can sometimes be useful in new installations or retrofits.

4.17 SHEET-METAL TOOLS

Often it is necessary for technicians to cut sheet-metal ductwork during installation or service. There are a variety of tools available that can make this much easier.

CAUTION

Always wear gloves when cutting or handling sheet metal.

Tin and Aviation Snips

Tin snips are used for making straight or circular cuts in sheet metal. The scissor-type tin snips have been used for years (Figure 4-84), but they have been replaced in recent years with the aviation-type tin snips (Figure 4-85). The aviation snip's hinged joint and serrated cutting edge have greatly improved the tin snip's use.

Aviation snips are available for right hand, left hand, or straight cuts. For example, the right-handed snips are

Figure 4-84 Scissor-type tin snips. (Courtesy of Terra Community College HVAC Program, Fremont, Ohio)

Figure 4-85 Aviation-type tin snips. (Courtesy of Terra Community College HVAC Program, Fremont, Ohio)

designed so that the scrap material is bent up and away from the cut, leaving the right-hand side of the sheet metal flat and smooth. They can also be used to cut right-hand curves or circles. The left-hand snips are used for cuts in the opposite direction. Straight snips may bend the edges of the cut sheet metal slightly upward and downward.

TECH TIP

Often the right-handed aviation snip's handles are green, the left-handed aviation snip's handles are red, and the straight aviation snip's handles are black. But these are not standardized colors and may vary from one tool manufacturer to another.

Offset-handled aviation snips are designed to keep your hand as far away from the sharp cut edge of the sheet metal as possible (Figure 4-86).

Nibblers

The nibbler is a powered hand tool that uses a circular punch and die to remove small crescent-shaped pieces of sheet

Figure 4-86 Offset-handled aviation tin snips. (Courtesy of Klenk Tools, A Division of Everhard Products, Inc.)

metal to produce a cut. Nibblers are available with fixed or swivel heads. The fixed head tool can be used for making straight cuts or can be guided around a curve or circle. A swivel head allows for easy following of curved lines or circles.

The nibbler leaves a very flat edge on the cut sheet metal, but it produces a small kerf of removed metal. A kerf is the gap being formed by the cutting tool. It is important that you provide for kerf width when laying out the dimensions for a cut to ensure that the part does not wind up being too small.

A nibbler cut must be started on an edge of the metal. To start a nibbler cut in the middle of a surface, a hole must first be drilled, so that the punch and die can be started on the edge of the hole.

CAUTION

Large quantities of sharp crescent-shaped chips are produced by a nibbler. Use a vacuum cleaner or brush to clean up the chips in your work area, because they can get stuck in your shoes and clothing. Be careful that chips stuck in your shoes do not damage your customer's floor. Be sure that chips stuck in your clothes do not scratch you.

Figure 4-88 Duct stretcher. (Courtesy of Klenk Tools, A Division of Everhard Products, Inc.)

Figure 4-87 Hand seamers. (Courtesy of Terra Community College HVAC Program, Fremont, Ohio)

Hand Seamers

Hand seamers are used to bend the edge of sheet metal (Figure 4-87). The edge of sheet metal is often bent to form a smooth edge, to make a slip joint, and/or to form a flange.

Duct Stretcher

A duct stretcher is used to pull a slip joint together when assembling rectangular sheet-metal duct. The tool's rollers (wheels) fit into the sheet-metal bends that form the slip joint and allow you to leverage them together so the drive cleat can be installed (Figure 4-88).

4.18 PIPING AND TUBING TOOLS

Unit 24, Piping and Tubing, describes the procedures and tools used for bending, cutting, flaring, and swaging in detail. Therefore, only a brief description of the tools is provided in this unit.

Tubing and Pipe Cutters

Soft copper tubing comes in rolls, while hard copper tubing comes in straight lengths. Tubing cutters can be used for either type of tubing and use a hardened steel rolling

Figure 4-89 Tubing-cutter. (Courtesy of Terra Community College HVAC Program, Fremont, Ohio)

cutter (Figure 4-89). Pipe cutters leave a small burr inside the cut end of pipe and tubes. As the cutter is rotated around the pipe, the cutting tool does not remove metal but simply forces an ever-deepening groove into the pipe or tube surface until it has been cut through. This burr must be removed, and there are deburring tools made for this purpose.

There are a number of different types and sizes of tubing cutters. Standard tubing cutters will cut tubing ranging in size from $\frac{1}{8}$ in to 1 in diameter. Larger tubing-cutting tools are available to cut tubing up to a 4-in diameter. Larger diameter tubing is usually cut with a portable band saw or other such power tool.

There are small diameter and compact cutters that can be used in tight or limited spaces (Figure 4-90). These cutters are a little more difficult to use, but they work very well

Figure 4-90 Compact tubing cutters $\frac{1}{8}$ in to 1 $\frac{1}{8}$ in OD and $\frac{1}{8}$ in to $\frac{5}{8}$ in OD.

Figure 4-91 Spring-type tubing bender. (Courtesy of Terra Community College HVAC Program, Fremont, Ohio)

when cutting tubing that is close to other tubes or otherwise has restricted access. Another type of tubing cutter sits around the tubing, and a ratcheting mechanism turns the cutter around as the handle is moved back and forth.

Spring and Hand Benders

A spring bender is made up of a coil steel spring. It slips over the tube being bent and provides lateral support to the side of the copper tube as it is bent. This lateral support prevents the tubing from crimping by keeping the tube relatively round (Figure 4-91). Different-sized spring-bending tools are available to fit various-sized refrigeration tubing. Spring-bending tools are limited to smaller tubing sizes.

Hand benders are tools that can be used to make accurate short radius bends in copper tubing (Figure 4-92). These tools are available for various diameters of copper tubing and in several different radii.

Flaring Tool

The end of a tube may be flared outward so that it can be secured using a flare nut and fitting. The two most popular flare fittings used in HVACR work are the National Pipe (NP) and the Society of Automotive Engineers (SAE) standard thread fittings. For these fittings to be used, a flare must be formed at the end of the tubing. To form the flare end of

Figure 4-92 Copper tubing hand bender. (Courtesy of Terra Community College HVAC Program, Fremont, Ohio)

Figure 4-93 Flaring block.

the tubing, a flaring block, shown in Figure 4-93, is placed around the end of the tube to be flared. The flaring block has various-sized openings for each tubing size to be flared.

Swaging Tool

Swaging is sometimes used to join copper tubing, but it is not as popular as flaring. It is the process of joining two pieces of copper tubing together by brazing or soldering without the use of fittings. The end of one piece of copper tubing is expanded so that the other piece will fit into it. Hand-punch swaging tools of different sizes are shown in Figure 4-94.

Tubing Brushes

It is often necessary to clean oxides, oil, or dirt off of copper tubing so it can be soldered or brazed. Tubing brushes (Figure 4-95a) come in a variety of sizes for cleaning out the inside of fittings. Figure 4-95b shows three sizes of tubing

brushes. One end is designed to clean the outside of the pipe, and the other end is designed to clean the inside of the fitting. These are available in sizes to fit most standard air-conditioning and refrigeration tubing.

UNIT 4—SUMMARY

All HVACR installation and service technicians use a wide variety of tools daily in the course of doing their jobs. Tools are a significant investment, and keeping them in good working condition is important. These tools must be cared for as prescribed by their manufacturer's instructions so they work properly and provide years of dependable service.

Using the proper tool for the proper job is important, because misusing tools can damage the tool and may be hazardous to you. For example, striking a mushroomed chisel with a hammer may send fragments flying. Avoid putting dirty tools back in your tool kit. Cleaning the tools after each use will make the next job go smoother.

From time to time, new tools are introduced that may help speed up your work. Watch trade journals and supply houses for advertisements for these new items. Talking with other technicians to see if any of them have used the new tools before investing your money in them can save you both time and money.

UNIT 4—REVIEW QUESTIONS

1. Why is it important for an HVACR technician's tools to be clean and organized?
2. Describe some of the features available on service valve wrenches.
3. What are the most common sizes of sockets?
4. Explain how socket handles are sized.
5. When should a breaker-bar socket wrench handle be used?
6. Why is it important that the same force be used when tightening nuts and bolts on compressors?
7. What is a good practice to follow when tightening bolts with a torque wrench?
8. How does a flare-nut wrench differ from a box wrench?
9. Explain the technique that should be used when using an adjustable wrench.
10. How does the tubing cutter cut?
11. What is a deburring tool used for?
12. Can you sometimes use a screwdriver as a chisel and pound it with a hammer?
13. Should pliers be used to tighten or loosen brass fittings? Why or why not?
14. Why are tubing brushes used?
15. List some of the safety precautions to be observed when using power tools.
16. What is the proper way to hold a hammer?
17. What two sizes of pipe wrenches are recommended for refrigeration installation and service work?
18. What type of wrench should typically be used on the screws on fan pulleys and fan blade hubs?
19. When would a nut driver typically be used?
20. What types of pliers are primarily used for mechanical HVACR work?
21. Electrical pliers should only be used for cutting what material?
22. How is cutting accomplished when using a hacksaw?
23. How are files and vises used in refrigeration work?
24. What are hand seamers, and when are they used?
25. What are the three different types of aviation snips?

UNIT 5

Screws, Rivets, Staples, and Other Fasteners

OBJECTIVES

After completing this unit, you will be able to:

1. explain how threaded fasteners are used in the HVACR industry.
2. explain size and length measurement as used with screws.
3. identify screw types and heads.
4. explain NC and NF screw threads.
5. explain how and why rivets are used.
6. demonstrate the use of HVACR duct staples.

5.1 INTRODUCTION

Assembling HVACR systems, components, and equipment requires technicians to use a variety of fastening devices. You might use a sheet-metal screw on ductwork or a condenser panel or a bolt to hold a head on a compressor. The range of items is extensive, and this unit does not cover all of the fasteners you may encounter in your career. It does cover the most commonly used fasteners, the ones you are most likely to see on a regular basis.

5.2 SCREWS AND BOLTS

Screws and bolts are both types of threaded fastener. Screws are typically smaller in diameter and length than bolts. In addition, screws may or may not thread into a nut. Typical types of screws are sheet-metal screws, wood screws, and machine screws. Sheet-metal screws are the most commonly used threaded fasteners in the HVAC industry. Wood screws are sometimes used in HVAC work to attach hanging straps to wooden rafters. Machine screws have standard threads and screw into nuts or prethreaded holes. Machine screw threads are available with coarse or fine threads in both standard and metric diameters (Table 5-1).

5.3 SHEET-METAL SCREWS

A typical specification for a sheet-metal screw might be ½-in #8 hex sheet-metal screw (half-inch #8 hexagonal-head sheet-metal screw) (Figure 5-1). The length of a screw is given from the tip of the screw to the base of the head of the screw or level with the top for flat-head screws (Figure 5-2). The most commonly used lengths of screws in HVAC are ½ and ¾ in (13 and 20 mm) in length. The diameter of a screw is given as a standard number.

Figure 5-1 Number 8, 1/2-in, hex-head sheet-metal screw.

Figure 5-2 Screw length.

Number 8 and number 10 screws are the most commonly used diameter sizes in the HVAC trade.

The hex-head sheet-metal screw shown in Figure 5-3a,b with (a) or without (b) a screwdriver slot are commonly used in the HVAC industry. The 1/4-in and 5/16-in (6 mm and 8 mm) hex-head sheet-metal screws are the most commonly used sizes in the field.

Pointed

Pointed sheet-metal screws, shown in Figure 5-4a, are often referred to as self-starting. This is because they can be spun into sheet metal without having to predrill a hole. Self-starting sheet-metal screws can be used on sheet metal ranging from 30 gauge through 18 gauge.

Self-Threading

Self-threading sheet-metal screws must have a pilot hole drilled into the metal before these screws are used. A small notch at the tip of the screw acts as a thread tap to cut the thread into the metal as the screw is being installed. Self-threading sheet-metal screws can be used in sheet metal ranging from 16 gauge to 1/8 in thickness. The threads on the self-threading screw of Figure 5-4b can tap a hole in 16-gauge sheet metal. The threads of the self-threading sheet-metal screw in Figure 5-4c are more closely spaced, and this screw could thread a hole in 1/8-in sheet metal.

Round-Tipped Sheet-Metal Screws

Round-tipped sheet-metal screws like the one shown in Figure 5-4d are often used on electrical panels or within

Figure 5-3 Sheet-metal hex-head screws: (a) with flat-blade slot; (b) without flat-blade slot.

Figure 5-4 Common types of screws used with HVAC work: (a) self-starting; (b) self-threading; (c) self-tapping; (d) round tipped; (e) self-drilling.

electrical panels to hold components in place. The tip of these screws is rounded and the end is not threaded. This protects against accidental stripping or shorting of wires within the electrical panel.

Self-Drilling

Self-drilling sheet-metal screws have a tip built like a small drill bit, as can be seen in the inset in Figure 5-4e. Self-drilling sheet-metal screws predrill the hole as the screw

goes in. Self-drilling sheet-metal screws can be used in metal thicknesses from 30 gauge to 16 gauge.

TECH TIP

The purpose of using round-tipped sheet-metal screws is to eliminate the possibility of a sharp point damaging electrical wire insulation.

An electric drill with a magnetic nut driver can be used to spin in self-starting and self-tapping sheet-metal screws. Self-starting sheet-metal screws are commonly used for on-site sheet-metal duct fabrication and installation. When using an electric drill with self-starting or self-tapping sheet-metal screws, the technician must be careful not to strip out the screw by overtightening it. Practice is required to develop the skill required to stop the drill the moment the screw is tight without overtightening. Some electric drills have torque adjustments, such as the dial on the drill in Figure 5-5, that allow the operator to set the drill so that it will apply enough force to sink the screw into the sheet metal but not strip it out.

SERVICE TIP

When using a magnetic nut driver and a drill, be certain that the head of the screw is completely in the end of the nut driver. If the nut is not completely in or is in at a slight angle, the screw head can slip inside the nut driver. This will quickly hollow out the end of the nut driver, rendering it useless.

Flat-blade screwdrivers and Phillips-head screwdriver tips may be used on some sheet-metal screws. The flat-blade screwdriver tip works well when manually removing or inserting screws, but it is very difficult to keep the bit

Figure 5-5 Cordless electric drill with adjustable torque chuck.

Figure 5-6 Common types of screw heads: (a) hex; (b) round; (c) pan; (d) flat; the bottom half of the figure shows how each screw will be represented in a drawing.

aligned in the slot if a drill on a power screwdriver is being used. Phillips-head screws can be used with a Phillips bit chucked in a drill or power driver more successfully than the flat-head-type bit. Unfortunately, when the screwdriver bit begins to wear, it is more difficult to tighten and loosen screws.

Screw Head Design

Screws can have several different head designs, shown in Figure 5-6, including hex (a), round (b), pan (c), and flat (d). Hex-head screws are the most common type used in HVACR work. They are used for almost everything inside and outside of the units. The round-head screw and the pan-head screw may be found inside electrical boxes and on electrical terminals. Round- and pan-head screws can have flat or Phillips slots, and some even have combination flat/Phillips slots, as shown in Figure 5-7. Phillips- and slot-head screws can be used in drills or power screwdrivers

Figure 5-7 Combination Phillips and slot-headed screw.

Figure 5-8 Screwdriving adapter: (a) with collar retracted to put Phillips bit into screw head; (b) with collar extended to keep contact between Phillips bit and screw head.

with an adaptor (Figure 5-8). The adaptor has a magnetic screwdriver bit inside a collar. The collar slides down over the screw so it can be held straight as it is driven in with a power screwdriver or drill. Wood screws are the most common type of flat-head screws. They are used to attach strapping to beams and joists.

Wood and Sheetrock Screws

Wood screws and sheetrock screws (Figure 5-9a,b) are often used in the HVACR industry to attach hanging straps to wooden structures. Wood screws for attaching hang-

Figure 5-10 Bolt, 3" \times 1/2" NC-13 hex head.

ing straps (a) are most often flat-head screws. Sheetrock screws are almost exclusively Phillips heads. The major difference in appearance between wood screws and sheetrock screws is that the wood screw is shiny and has a portion of the shank that does not have any thread. Sheetrock screws are almost always black, and their thread extends the full length of the screw.

5.4 BOLTS AND NUTS

Bolts and nuts have machined threads. These threads will only work when matched parts are used. A typical specification for a bolt would be 3" \times 1/2" NC-13 hex head, which is shown in Figure 5-10. The first dimension given, 3", is the length of the bolt. The second dimension, 1/2", is the outside or major diameter of the bolt. The letters NC refer to the fact that this is a national coarse threaded bolt. It has 13 threads per inch, and the bolt has a hex head. The length of the bolt is measured from the base of the head to the tip. The diameter of a bolt is measured across the threads. The type of thread is listed as either NC for national coarse or NF for national fine. Each standard-diameter bolt has a uniform number of threads per inch, depending on whether it is coarse or fine. Although most of the bolts used are hex-head bolts, other head designs include carriage bolt, square, and Allen wrench. Square-head and Allen wrench bolts are typically used on fans to hold the blades to the rotating motor shaft.

5.5 NAILS

Nails come in a variety of sizes, lengths, and materials and with different types of heads. The most commonly used nail material for HVACR work is steel, and they may be zinc coated to resist rusting.

Nail Types

Figure 5-11a,b illustrates some of the common nail types and sizes used in HVACR work.

- **Common nails** Large diameter, flat-headed nails used for general wood frame construction.
- **Box nails** Similar to common nails in shape and use but they are thinner in diameter.
- **Finishing nails** Small diameter, small-headed nails used to attach trim boards to door casings and floor molding. These nails are generally designed to be countersunk or recessed for a finished appearance.

Figure 5-11 (a) Common nails; (b) finishing nail. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

Nail Sizes

Penny is the term commonly used for nail sizes. It is abbreviated as “d” and is used with the wire gauge number. (Note: This notation is actually a carryover from English unit weight measurement. Even the penny coin was abbreviated “d.”) The wire gauge number refers to the size of the wire used to make the nail. The larger the number, the smaller the nail size will be. Some nails are sold with both their penny size and length, which can make choosing the correct nail size easier.

5.6 CONCRETE FASTENERS AND ANCHORS

The terms *concrete fastener* and *concrete anchor* are often used interchangeably; however, *fasteners* are nonstructural while *anchors* can be used for both nonstructural and structural attachments. Concrete fasteners can be grouped into two general categories: driven-in and predrilled. Anchors are almost always predrilled, but some can be preplaced before the concrete is poured.

Driven-in concrete nails can be installed using a hammer or with a gun and ballistic charge. The hammered-in concrete nails are usually short and work best when driven in with the fewest hammer blows. Repeatedly hammering of the nail can loosen it in the concrete.

Ballistic concrete nail guns may be trigger activated or hammer-strike activated. In both cases they use a small charge that resembles a .22-caliber blank cartridge to drive the nail in quickly. The nail lengths and cartridge power must be matched to the job so that the nail is driven into its desired depth.

CAUTION

Always wear proper eye and face protection when nailing, and read and follow all manufacturer's safety instructions. Special safety protection should always be used when driving ballistic concrete nails in anticipation of flying chips of cracking or exploding concrete.

Early concrete anchors used lead sleeves placed in a drilled hole, and these type of anchors are still used today. One drawback, however, is that the hole drilled into the concrete has to be a lot larger in diameter than the anchor. This means that the holes have to be accurately predrilled so they align with the part being attached. Newer types of anchors can fit into the same diameter hole as the anchor itself. This allows the preplacement of the part being attached, so hole alignment is not as much a problem. Figure 5-12a–c shows concrete anchors, drill bits, and the drilling through concrete for an anchor hole.

Figure 5-12 (a) Concrete anchors; (b) concrete drill bits; (c) drilling concrete anchor hole. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

TECH TIP

Concrete is the most widely used material on Earth. It is used for all types of construction. Masonry is a type of construction using bricks, stones, blocks, and so on. Masonry construction is held together with mortar or similar types of materials. Concrete fasteners can be used on most masonry construction.

5.7 RIVETS

A rivet is a small, unthreaded piece of metal that is installed through a predrilled hole. Once it is through the hole, the end of the rivet is enlarged so it will not fit back through the hole. The process of enlarging the end is called “upsetting the rivet.” Over the centuries, rivets that had to be upset by hammers were in common use, but today this type is seldom used. Pop rivets have replaced the older style of rivets.

Pop rivets are usually made out of aluminum, but other metals, including copper and stainless, are available. A variety of pop rivets is shown in Figure 5-13. A pop rivet has a central shaft that is placed in a pop rivet gun, shown in Figure 5-14. The sequence showing the installation of a rivet is represented in Figure 5-15. The central shaft is withdrawn

Figure 5-13 Pop rivets come in a variety of types and sizes.

Figure 5-14 Pop rivet gun.

Figure 5-15 Steps in pop riveting: (a) drill a hole; (b) insert a pop rivet into the hole; (c) depress the pop rivet gun handle to upset the rivet; (d) rivet stem pops off when blades are pulled tight and rivet is seated; (e) cross-section of pop rivet.

back through the center of the hollow rivet shaft. As the bead on the end of the center shaft is pulled through the rivet sleeve, the sleeve deforms outward. When the bead at the end of the central shaft is pulled snugly against the back side of the drilled metal, it pops off so that the nail-like shaft can be removed and discarded.

Pop rivets come in a variety of sizes, ranging from the most popular $\frac{1}{8}$ -in diameter up to $\frac{1}{4}$ -in diameter. The length of a pop rivet is determined by the distance from the tip to the head of the pop rivet. You should select a pop rivet that will extend through the joint materials by at least $1\frac{1}{2}$ times the diameter of the pop rivet. For example, a $\frac{1}{8}$ -in diameter pop rivet should extend through the material being joined by at least $\frac{3}{16}$ in, and a $\frac{1}{4}$ -in diameter pop rivet should extend $\frac{3}{8}$ in through the material.

SERVICE TIP

Usually rivets have limited field applications in the HVAC industry because of the time required to predrill the holes. However, a $\frac{1}{8}$ -in pop rivet will fit into a #8 sheet-metal screw hole. Placing one pop rivet in the corner of a panel will reduce the possibility of unauthorized people tampering with the system.

The best way to remove rivets without damaging the base metal is to drill them out. Pop rivets can be easily drilled

Figure 5-16 Steps in removing a pop rivet using a drill: (a) the drill bit should be slightly larger than the original pilot hole; (b) the drill only cuts out the rivet head; (c) the head and the shaft fall away.

using a bit slightly larger than the original shaft of the hole. As the drill cuts through the rivet head, the shaft of the rivet will be removed once the head has been cut free. Figure 5-16 shows the sequence of the drill bit next to the rivet (a), drilling out just the rivet head (b), and the pop rivet, with its head drilled out, falling away (c). Take care not to drill through and increase the size of the rivet hole.

SERVICE TIP

Sometimes the drill will grab the rivet and the rivet will spin. If this happens, you cannot drill out the rivet head. But by angling the drill bit slightly to one side, the bit will begin cutting again. Only angle the bit enough for it to start cutting. Too much angle may cause the bit to slip off of the head, damaging the finish of the part.

5.8 STAPLES

Staples hold by either driving their points into a soft material such as wood or by having the legs folded, as with a paper stapler. Staples come in one standard width (Figure 5-17). Staples can be purchased with a variety of lengths of leg, from $\frac{1}{4}$ in to $\frac{15}{16}$ in.

Specially designed staples are used to attach fabric or vinyl-backed duct insulation (Figure 5-18a). Duct staplers are designed so that the tips of the staple are bent outward as the staple is driven through the fabric (Figure 5-18b). Duct staples are the most commonly used device for attaching external insulation to sheet-metal ducts.

Figure 5-17 Staples come as preassembled strips.

5.9 TAPE

Two of the most commonly used types of tape in the HVACR industry are duct tape and electrical tape. Tape is manufactured to a variety of specifications, but new codes require that all duct tape meet UL 181 standards. The quality of tape used will directly affect the length of time it stays in place to seal the duct. For example, some vinyl gray duct tape is sold at deep discounts because it does not contain fabric reinforcement. There may even be a pattern embossed in the plastic to give it the illusion of having cloth reinforcement while no reinforcement exists.

Because of the heat in an attic, vinyl or cloth duct tape mastic will dry out over time and become hard and brittle. When this happens, no tackiness is left in the tape, and it simply comes loose (Figure 5-19). It is not a matter of *whether* the tape will dry out and fail but *when* it will dry out and fail. For this reason most codes require UL 181 for duct-closing systems. There are several different types of tape under the UL 181 listing. Each of these tapes has a different purpose (Table 5-2).

Aluminum pressure-sensitive tapes are easily formed to the surface, creating a tight fit. They have a rubber or acrylic adhesive that is protected on the roll with a paper backing. The paper backing is removed when the tape is being used (Figure 5-20). Cloth tapes have a Mylar coating and are designed for application on flex ducts (Figure 5-21). All approved UL 181 tapes must be identified with lettering on the face of the tape.

Figure 5-19 Always use the proper duct tape for the job. Improper duct tape will dry out and become loose as shown.

The adhesive on foil tapes is very tacky. If it is accidentally touched to any surface before it is in place it is difficult if not impossible to remove it. Foil tape comes with a paper backing to keep it from being stuck permanently to itself in the roll. This paper must be peeled back as the tape is applied to the surface. Once the tape is in place

Figure 5-20 Aluminum pressure-sensitive duct tape.

Figure 5-21 Mylar-coated pressure-sensitive duct tape.

it should be smoothed down securely to ensure a proper seal. Failure to wipe the tape down can result in air gaps beneath the tape, which will allow its mastic to dry out. Keeping duct tape securely in place over time is the only way to ensure that conditioned air does not leak out of the duct system.

Vinyl electrical tape is often referred to as electrical tape or simply black tape. As with duct tape, there is a range of quality in the tape available. A good vinyl electrical tape should have some stretch so it can form itself around the wires or connection. Too much stretch and the tape cannot be pulled tightly around the parts. The tape must resist heat without loosening or softening.

5.10 ADHESIVES

There are a number of adhesives used in HVACR work. The three general groupings of adhesives are mastics, glues, and caulk. Generally in HVACR work, mastics are used to seal large areas such as duct joints, glues are used to hold items together, and caulks are used to seal cracks. All three types of material are classified as adhesives. *Adhesion* is their ability to stick to a surface, and *cohesion* is their ability to stick to themselves.

When using any adhesive, it is important that the surface is clean, dry, and free of loose material. Any of these surface conditions can prevent adhesion. Some adhesives have reinforcing fibers to add to their cohesive strength, while others do not have reinforcing fibers.

Adhesives may be water based or use another type of volatile organic compound (VOC) as their solvent. Some VOCs are flammable, and others can produce hazardous fumes. Adequate ventilation must be provided to prevent the buildup of hazardous or explosive fumes in the work area.

Some adhesives are paintable, and some are not. Check to see whether the product you plan to use on any interior or exterior surfaces can be painted before you use

it. Not being able to paint the caulk can be a problem, especially when it is used around public areas, such as the trim around a supply grill and the like.

CAUTION

Always follow all manufacturer's instructions when using adhesives. Wear all personal protection equipment suggested by the manufacturer.

TECH TIP

If you pull a glued component apart and the glue comes off of the surface, that is an adhesion failure. If the glue separates itself, it is a cohesive failure.

5.11 TIE STRAPS (DRAW BANDS)

Tie straps, or draw bands, are usually made out of nylon and are widely used in the HVACR industry. Large sizes are used to secure flexible duct to start collars or boots, shown in the installation sequence in Figure 5-22a–d. These tie straps must be resistant to ultraviolet light (UV) and have a tensile strength of 150 lb and a service temperature of 165°F. When nylon straps are used on duct installations, a special tool called a strap tensioner must be used. The strap-tensioning tool pulls the strap tight, reducing the likelihood of air leaks and mechanically connecting the duct to the sheet metal boot or collar securely. Once the proper tension has been applied, a lever on the strap-tensioning tool extends a razor knife to cut off the unused nylon strap end.

Smaller ties are used to secure wires into bundles inside of units. When the nylon straps are used around electrical wires, they are simply pulled tight by hand or with a pair of pliers, and the unused portion is cut off, as shown in the installation sequence in Figure 5-23a–d.

SERVICE TIP

From time to time a tie strap may be put in place and only later is it found that it has to be removed. Ties may need to be removed when a wire must be added or removed from the bundle or when a duct needs to be cut shorter or straightened. Tie straps are expensive and must not be wasted. They can be removed easily, if the end has not been cut off, by placing the tip of a small screwdriver under the ratchet mechanism (Figure 5-24a,b). By putting just a little force on the corner of the screwdriver blade, the tie will be able to slip through the mechanism. Do not force the screwdriver tip under the mechanism. You can damage the ratchet, or the screwdriver could slip and stick your finger. As a precaution, you might want to use pliers to hold the strip the first few times you try this. Once the ratchet is released, use your thumb to slide the end up and off to remove the tie strap.

UNIT 5—SUMMARY

Thread gauges and screw and bolt size gauges are available to help you find the correct size of threaded fastener for the job. Never force a nut, bolt, or screw if it does not fit correctly. You can cross-thread the part and strip the threads, which can result in a significantly longer time to repair. You may also break off the bolt or screw in the part, which will require a lot of work to remove.

Although there are many different types and sizes of fasteners that can be used in HVACR work, you will find that the number and type you use on a regular basis is relatively small. The commonly used ones are the ones you will have in your tool bag and stock in your service vehicle.

Most HVACR parts houses carry the commonly used fasteners. You may need to go to a nut and bolt supply store to locate the specialty fasteners you need for some jobs.

UNIT 6

Measurements

OBJECTIVES

After completing this unit, you will be able to:

1. list the four physical properties that are commonly measured.
2. list common units used in the inch-pound system.
3. explain the basic concept of the SI system.
4. explain the concept of rate measurement.
5. calculate the area of a surface.
6. calculate the volume of a space.
7. estimate length and area based on standard building material dimensions.

6.1 INTRODUCTION

Standard measures are necessary for people to communicate the quantity and size of objects, areas, substances, energy forms, and just about everything that we have to deal with in life. Without standard measures, the only way for someone to get an idea of something's size would be to see it. Measurement standards are crucial to any form of contracting work, including heating, air conditioning, and refrigeration, so technicians must be familiar with many types of measurement. There are four physical properties that must often be measured: distance, area, volume, and weight. Technicians also measure things that are not physical properties, such as water flow or air flow. Flow measurements measure a quantity over time. In the United States we currently use a mix of two measurement systems: customary units based on the inch-pound system and SI units based on the metric system.

6.2 CUSTOMARY MEASUREMENTS IN THE UNITED STATES

The United States is the last industrialized nation still using traditional customary measurements for most of our day-to-day work. Our customary system is not really a system at all but a collection of different units passed down from several different cultural traditions. The British have been the largest influence, but measures they passed on were adopted from several different cultures, including Celtic, Roman, Saxon, and Norse. Our system is sometimes called the inch-pound system after the units we use for small linear measurement and weight. Table 6-1 lists many of the most common customary measures used today in the United States.

Table 6-1 Customary U.S. Measurements

Property	Unit	Relationship to other Units	Example
Weight	Grain	7,000 Grains in a pound	The weight of water vapor in a pound of air is measured in grains
Weight	Ounce	16 ounces in a pound	Refrigerant charge in refrigerators is in ounces
Weight	Pound	2,000 pounds in a ton	Refrigerant charge in large units is in pounds
Weight	Ton	2,000 pounds in a ton	A 1/2 ton pickup can carry 1,000 pounds
Length	Inch	12 inches in a foot	Filter dimensions are given in inches
Length	Foot	3 feet in a yard	Duct length is given in feet
Length	Yard	1,760 yards in a mile	A run in football is measured in yards
Length	Mile	5,280 feet in a mile	Distance to the job is given in miles
Area	Square Inch	144 square inches in a square foot	The area of a grille is measured in square inches
Area	Square Foot	9 square feet in a square yard	The area of a room is measured in square feet
Area	Acre	43,560 square feet in an acre	Land area is measured in acres
Dry Volume	Cubic Inch	1,728 cubic inches in a cubic foot	Compressor displacement is measured in cubic inches
Dry Volume	Cubic Foot	27 cubic feet in a cubic yard	The space in a room is measured in cubic feet
Dry Volume	Yard (Cubic Yard)	Space occupied by a cube 1 yard in all dimensions	Sand, gravel, and concrete are sold by the cubic yard

6.3 LINEAR MEASUREMENT

Linear measurements are used to indicate distance. Linear means that we are measuring a line. Remember, the shortest distance between any two points is a straight line. When we say that the ceiling is 8 feet high, we are stating that a line drawn from the floor to the ceiling would be 8 feet long. Anything that can be measured using a line can be expressed as a linear measurement. Typically, distance is measured in yards, feet, and inches using the traditional English system of measurements. There are 3 feet in 1 yard and 12 inches in 1 foot (Figure 6-1). Longer distances are measured in miles. The term *mile* derives from the Roman Legion. “Mille passuum” in Latin means a thousand paces. A mile was the distance they would cover in a thousand paces. Today, a statute mile is equal to 5,280 feet.

Figure 6-1 One yard = 3 feet; one foot = 12 inches.

Figure 6-2 Close-up of ruler with dimension lines showing different heights.

Small measurements are taken in fractions of an inch. Each division is half of the previous division, producing common units of $1/2$, $1/4$, $1/8$, $1/16$, and $1/32$. Extremely small dimensions used in machining are given in thousandths of an inch instead of fractional sizes. Traditional rulers often show the relationship of the divisions by making the lines for each division progressively smaller to make recognizing the different units easier (Figure 6-2).

TECH TIP

Many people find the relationship of fractions with different denominators confusing. To compare two fractional sizes, multiply the bottom number (denominator) of the fraction with the smaller number on the bottom by 2 until it equals the denominator of the other fraction. Then multiply the top number (numerator) by 2 the same number of times. For example, comparing $3/4$ inch and $11/16$ inch: multiply 4 by 2 twice to get 16 ($2 \times 4 = 8$, $8 \times 2 = 16$). Then multiply 3 by 2 twice to get 12 ($2 \times 3 = 6$, $6 \times 2 = 12$). Now you can easily see that $12/16$ is larger than $11/16$.

6.4 AREA MEASUREMENT

Area is used to express two-dimensional measurement of a surface. Examples of items that are measured by area would be a desktop, a plot of land, and the floor of a building. Area measurements require two dimensions. The term *square* is used when describing an area because area measurements are broken down into several squares of a certain size. For example, a square foot represents the area of a square with sides of 1 foot. An area of 10 square feet would be equal to the area covered by ten of these 1-x-1-foot squares (Figure 6-3). Technicians sometimes need to convert between square feet and square inches. It might be logical to assume that since there are 12 inches in a foot, that there are 12 square inches in a square foot. However, this is incorrect. Indeed there are 12 inches in a foot, and since a square foot is 1 foot wide and 1 foot long; a square foot can be divided into 12 rows of boxes with 12 boxes in each row. Multiplying 12×12 you arrive at the factor for converting square feet to square inches: 144 (Figure 6-4). To convert any square measurement to another, multiply the area by the linear conversion twice, once for each dimension. For instance, to convert square yards to square feet, the number of square yards would be multiplied by 3 twice, since there are 3 feet in a yard. 5 square

Figure 6-3 Drawing showing 10 sq ft made up of 10 squares.

Figure 6-4 Drawing showing 144 sq inches in sq ft.

yards can be converted to square feet by multiplying $5 \times 3 \times 3 = 45$ square feet. Of course you could also multiply 5 times 3 squared and get the same result. When we talk about a number squared, we just mean the number multiplied by itself. In the case of 3, 3 squared equals 9, so 5 square yards $\times 9 = 45$ square feet.

Common Uses

The floor space in your home is measured in area. Floor space is generally measured in square feet, while filter, grille free, and duct work cross-sectional areas are normally given in square inches. To convert from square inches to square feet, divide by 144. For example, a 16×16 filter has an area of 256 square inches ($16 \times 16 = 256$). To convert this to square feet: $256/144 = 1.78$ square feet (Figure 6-5).

6.5 VOLUME MEASUREMENT

Volume is another physical measurement you are likely to deal with. Linear measure is used for lines, area for surfaces, and volume for things that take up space. All objects exist in three dimensions, one more dimension than can be expressed by area measurement. To find volume, you need

Figure 6-5 There are 256 square inches in a 16×16 filter.

Figure 6-6 Drawing showing little cubes for cubic measurement.

length, width, and height. For area we use square measurement; for volume we use cubic measurement. Remember, square measurement subdivides a surface into several equally sized square sections, such as square feet or square inches. Cubic measurement subdivides an object or space into equally sized cubes, such as cubic feet or cubic inches (Figure 6-6). To find the volume of anything, multiply the area of its base by its height. For example, a box with a base of 4×6 inches and a height of 10 inches would have a base area of 24 square inches ($4 \times 6 = 24$). Multiplying the 24-square-inch base area times its height of 10 inches would yield a volume of 240 cubic inches ($24 \times 10 = 240$).

Common Uses

A cubic yard is a volume equal to the volume of a box that is 1 yard (3 feet) in all dimensions. Cubic yards are typically used to measure large volumes of material, such as dirt, sand, and concrete. Often, the “cubic” prefix is dropped, so that contractors order concrete by the yard. In air-conditioning work, cubic measurement is used to express airflow. Airflow is measured in cubic feet per minute, CFM. When air is flowing at the rate of 1 CFM, the air will fill up a 1-cubic-foot box in 1 minute (Figure 6-7). The volume inside electrical connection and junction boxes is given in cubic inches (Figure 6-8).

Figure 6-7 Air filling up a 1-cubic-ft box in one minute equals 1 CFM.

Electrical Box Specifications	
Dimensions in inches	Volume in cubic inches
$3 \times 2 \times 1.5$	7.5
$3 \times 2 \times 2$	10.0
$3 \times 2 \times 2.25$	10.5

$3 \times 2 \times 3.75$	14.0
$3 \times 2 \times 3.5$	18.0

Figure 6-8 Spec sheet for electrical box showing volume in cubic inches.

6.6 LIQUID VOLUME MEASUREMENT

Liquid volumes are more commonly measured in units designed specifically for measuring them. In the United States we use gallons, quarts, pints, cups, and ounces. Note that these units are not “cubed” because they are inherently a cubic measurement. A cubic foot is equal to 7.48 U.S. gallons, making a U.S. gallon approximately 1/8 of a cubic foot. Gallons are divided into quarts, with 4 quarts equal to a gallon. Quarts are divided into pints, with 2 pints equal to a quart. And pints are divided into cups, with 2 cups equaling a pint. Finally, cups are divided into ounces, with 8 ounces equaling a cup. Note that fluid ounces are a measure of volume, not weight. Table 6-2 shows the relationship of all these fluid volume measurements.

Table 6-2 Customary Liquid Volume Measurement

Unit	Relationship to Other Units	Example
Ounce	8 ounces in a cup	Compressor oil is measured in ounces
Cup	2 cups in a pint	Liquid measure in recipes are in cups
Pint	2 pints in a quart	PVC cement is sold in pints
Quart	4 quarts in a gallon	Motor oil is sold in quarts
Gallon	128 ounces in a gallon	Refrigeration oil is sold in gallons

Common Uses

In air conditioning we normally measure oil containers in quarts or gallons, while compressor oil quantities are often stated in fluid ounces. Water flow is normally stated in gallons, as in gallons per minute, GPM.

SERVICE TIP

To determine how many quarts of oil are required for an oil charge stated in fluid ounces, divide the quantity of fluid ounces by 32. For example, an oil charge of 64 ounces would require 2 quarts: $64 \text{ fluid ounces} / 32 = 2 \text{ quarts}$.

6.7 AREA AND VOLUME OF ROUND OBJECTS

The discussion so far has been about areas and volumes for rectangular objects. The formulas that work for rectangles do not apply to circles.

Area of a Circle

The area of a circle is found by using the formula: $\text{area} = \pi r^2$ where $\pi = 3.14$ and r = circle radius (Figure 6-9). The radius of a circle is the distance from its center to the outside of the circle. This amounts to half of the diameter, which is the distance across the circle.

Example: Calculate the area of a circle with a 12-in diameter. The formula is $3.14 \times 6^2 = 3.14 \times 6 \times 6 = 3.14 \times 36 = 113$ square inches (approximately). The area of a 10-in diameter circle would be $3.14 \times 5^2 = 3.14 \times 5 \times 5 = 3.14 \times 25 = 78.5$ square inches (approximately). Notice how much smaller the area of the 10-inch circle is than the area of the 12-inch circle.

Circumference of a Circle

Occasionally it is necessary to determine the circumference of a circle. The circumference is the distance all the way around the outside of the circle (Figure 6-9). The formula for

Figure 6-9 Drawing showing radius, diameter, and circumference of circle.

Figure 6-10 A cylinder with 6-in diameter and 10-in height.

the circumference of a circle is πd , where $\pi = 3.14$ and $d =$ the circle diameter. The circumference of a 12-inch circle would be $3.14 \times 12 = 37.7$ inches (approximately).

Volume of a Cylinder

Calculating the volume and surface area of round objects is somewhat more complicated than calculating the volume of boxes. Round objects include spheres, cones, and cylinders. For our purposes, we only discuss cylinders. The volume of any regular solid can be determined by multiplying the area of its base times its height. A regular solid is one that keeps the same shape all the way up. Boxes and cylinders both fit into this category, while spheres and cones do not. Therefore, to find the volume of a cylinder, first find the area of the circle that forms its base. Then multiply this area by the height of the cylinder.

Example: Calculate the volume of a cylinder that has a diameter of 6 inches and a height of 10 inches. First, calculate the area of the circle that forms the base: $3.14 \times 3^2 = 3.14 \times 3 \times 3 = 3.14 \times 9 = 28.3$ square inches (approximately). Next, multiply this area by the height: $28.3 \text{ square inches} \times 10 \text{ inches} = 283 \text{ cubic inches}$. (approximately) (Figure 6-10).

6.7 WEIGHT MEASUREMENT

Weight is measured in pounds and ounces. For most measurements, we use the avoirdupois pound, which is divided into 16 ounces. Large weights are measured in tons. A ton is equal to 2,000 avoirdupois pounds. Grains are used for very small weight measurement. A grain was originally the weight of a single grain of barley. We use grains in air conditioning to measure the weight of water in the air. The avoirdupois pound is equal to 7,000 grains. Another weight system is used for precious metals: troy pounds and ounces. A troy pound is equal to 5,760 grains and is divided into 12 troy ounces. Silver brazing material is often sold by the troy ounce because of its silver content. Note that a troy ounce is 480 grains, which is larger than a "regular" avoirdupois ounce of 437.5 grains. However, a troy pound is smaller than a "regular" avoirdupois pound.

Figure 6-11 Refrigerant charge can be listed in pounds, ounces, or pounds and ounces.

TECH TIP

Early refrigerated food preservation was done with ice. Refrigeration was measured by the amount of ice required. In the United States, refrigeration capacity is still stated in tons. A ton of refrigeration is the amount of cooling accomplished by melting 2,000 pounds (a ton) of ice over a 24-hour period. This is how a measurement for weight also became a measurement of refrigeration capacity.

The quantity of refrigerant in a system can be given in ounces, pounds and ounces, or decimal pounds. Most charging scales do not allow technicians to enter ounce quantities greater than 16, so charges specified in ounces must be converted to pounds and ounces if the charge exceeds 16 ounces. Divide the number of ounces by 16 to arrive at the weight in pounds. For example, a charge of 76 ounces would be $76 \text{ ounces} / 16 = 4.75$ pounds. This would work for a scale that reads in decimal pounds. For a scale that requires the weight in pounds and ounces, convert the decimal portion of the answer back to ounces by multiplying by 16: $0.75 \times 16 = 12$ ounces. This charge can be stated three ways: 76 ounces, 4.75 pounds, or 4 pounds, 12 ounces (Figure 6-11).

6.8 COMPOUND MEASUREMENTS

Distance, area, volume, and weight are all quantitative measurements; they measure the quantity or amount of something. How long, how high, the amount of space something occupies, or how much it weighs are all quantities. Volume and weight are often used to measure the amount of a substance. But neither measurement by

itself tells the whole story. This is illustrated by an old joke: “Which is heavier, a pound of lead or a pound of feathers?” Of course, they weigh the same since the question stated “a pound” as the quantity. The joke is that many people instinctively answer that the lead is heavier. Of course, lead is heavier than feathers if you compare an equal volume of each. However, the question was comparing an equal weight. If the question is rephrased, “Which weighs more, a cubic foot of feathers or a cubic foot of lead?” the lead would be heavier. A compound measurement measures two or more properties and compares them to each other. It is useful to compare the weight and volume of substances when you need to know “how much” you have. Three comparisons are used for this purpose: density, specific volume, and specific gravity. Density compares weight to volume, specific volume compares volume to weight, and specific gravity compares the density of a substance to the density of air or water. Unit 7, Properties of Matter, discusses these in more detail.

Pressure

Pressure is a compound measurement. It compares force to the area supporting the force. The pressure on any surface can be determined by dividing the total amount of applied force by the area. An object that weighs 100 pounds and has a base of 100 square inches will exert a force of 1 pound per square inch: $100 \text{ pounds} / 100 \text{ square inches} = 1 \text{ pound per square inch}$. We abbreviate this as 1 psi. If the object weighed 100 pounds but had a base area of only 50 square inches, the pressure would be 2 psi because the same weight is supported by a smaller area: $100 \text{ pounds} / 50 \text{ square inches} = 2 \text{ psi}$. If the same 100 pounds was supported by a larger base of 200 square inches, the pressure would be only 0.5 psi: $100 \text{ pounds} / 200 \text{ square inches} = 0.5 \text{ psi}$. To calculate pressure, divide the force by the area. Unit 11, Pressure and Vacuum, discusses pressure in more detail. In air conditioning, pressure is most commonly measured in psi. Figure 6-12 shows a typical pressure gauge.

6.9 RATE MEASUREMENTS

All the measurements discussed up to now have been static measurements. That is, what is being measured does not change. However, air conditioners are dynamic

Figure 6-12 A typical pressure gauge.

devices. Many performance characteristics that technicians need to measure are moving. Measuring something that is moving is done by rate. A rate measurement is a compound measurement that compares a quantity with time. In air-conditioning systems, airflow, water flow, and even a system’s heating or cooling capacity are stated as a rate. The air flowing through an air-conditioning unit is a perfect example. The output of a fan is measured in cubic feet per minute, describing the volume of air in cubic feet that the fan moves every minute. A common rate measurement for water flow is gallons per minute, describing the number of gallons a pump can move in a minute. System capacity is stated as a rate of heat flow in BTUs per hour. This is the amount of heat produced or rejected in 1 hour of operation. Two common electrical measurements are also rates: amperes and watts. Amperes measure the flow of electrons; an amp is the flow of 1 coulomb of electrical charge per second. Watts measure the rate of electrical power; a watt is the transfer of electrical energy at the rate of 1 joule per second.

Water Flow

Rate measurements require both a quantity measurement and a time measurement. When measuring water flow, gallons represent the quantity while minutes or hours are used for time. A reasonably accurate measurement of water flow can be obtained by collecting water in a container for a minute. The number of gallons collected in a minute represents the rate in gallons per minute. For a more accurate estimate, collect water for a longer period of time and divide the gallons of water collected by the number of minutes. Water-flow gauges are available that allow technicians to read the water flow just by looking at the gauge (Figure 6-13).

Figure 6-13 A water-flow gauge.

AIR LEAVES AT 12:01

AIR ENTERS AT 12:00

Figure 6-14 Air moving at 100 FPM takes exactly one minute to travel 100 feet.

Airflow

You can't really "collect" the air to check the rate of airflow. However, it is possible to check the speed of the air and use it to determine the amount of airflow. Speed is typically stated as a rate. A speed of 50 miles per hour indicates that a car traveling at that speed for an hour will cover a distance of 50 miles. Airspeed, or velocity, is measured in feet per minute. Feet per minute (FPM) describes how far the air will travel in a minute (Figure 6-14). This still does not really measure how much airflow there is, just how fast it is moving. To determine the volume of the air, multiply the velocity of the air times the area of the hole it is leaving. Air traveling at a rate of 100 feet per minute through a 1-square-foot opening will make a column of air with a volume of 100 cubic feet in 1 minute. Example: Calculate the airflow if air is leaving a 24 × 36-inch hole at a velocity of 50 FPM (feet per minute). The area of the hole is calculated by multiplying 24 inches × 36 inches = 864 square inches. Convert square inches to square feet by dividing by 144: 864 square inches/144 = 6 square feet. Alternately, you can convert the dimensions to feet before multiplying: 24/12 = 2 ft, 36/12 = 3 ft, 2ft × 3ft = 6 square feet. The airflow in CFM (cubic feet per minute) is calculated: 50 FPM × 6 square feet = 300 CFM.

Heat Flow

Heat quantity is measured in British thermal units, abbreviated BTU. A BTU is defined as the amount of heat required to raise 1 pound of water 1 degree Fahrenheit at atmospheric pressure. BTUs are calculated by multiplying the weight of water by the temperature change in degrees Fahrenheit. For example, raising 100 pounds of water 50 degrees would require 5,000 BTUs: 100 pounds × 50 degrees = 5,000 BTUs. BTUs are a quantity, not a rate. The amount of time required to raise the water temperature is also needed to specify the rate. If this is accomplished over the period of an hour the rate would be 5,000 BTUs per hour. If the same amount of temperature rise took 2 hours, the rate would be 5,000 BTUs/2 hours = 2,500 BTUs per hour. Unit 8, Types of Energy and Their Properties;

Unit 9, Temperature Measurement and Conversion; and Unit 10, Thermodynamics, discuss temperature, heat, and heat flow measurements in greater detail.

TECH TIP

Temperature is not a measurement of heat quantity. Temperature alone cannot measure the amount of heat in a substance. Instead, temperature measures heat intensity. It measures the average kinetic energy of the molecules in a substance; it is not affected by the amount of the substance. A 16-oz glass of water and an 8-oz glass of water can be the same temperature even though the 16-oz glass contains more heat due to the greater volume of water.

6.10 SI MEASUREMENTS

The International System of Units, abbreviated SI, has become the accepted international system of measurement. All science is done in SI units, and most international trade is done using SI units. Any company that wants to market its products outside of the United States offers unit specifications in SI (Figure 6-15). SI is the implementation of the metric system, which was first adopted in France in 1791. The system was developed around three core ideas: there should be only one unit for each type of measurement, the units should logically relate to each other, and all subdivisions are in base 10. Smaller and larger quantities are expressed by applying prefixes that stand for different powers of 10. Only a few prefixes are commonly used today. For small measurements, *centi-* is used for 1/100th and *milli-* for 1/1,000th. For example, a centimeter is 1/100th of a meter: there are 100 centimeters in a meter. A milliliter is 1/1,000th of a liter: there are 1,000 milliliters in one liter. For large measurements, *kilo-* is used to indicate 1,000 of something and *mega-* is used to indicate a million of something. For example, a kilometer is equal to 1,000 meters and a megaohm is equal to 1 million ohms.

Base Units

The base units originally defined in the metric system were the meter for length, the gram for weight, and the liter for liquid volume. The milliliter was defined as the volume of 1 cubic centimeter, and the gram was defined as the weight of that same quantity of water. This tied distance, volume, and weight all neatly together. Today, SI uses seven defined base units:

- Meter for length
- Kilogram for mass
- Second for time

Table 6-3 Common SI Prefixes

Prefix	Represents	Units	Example
micro	One millionth	microamps	Flame rod output is measure in microamps
milli	One thousandth	millivolt	Thermocouple output is measure in millivolts
kilo	One thousand	kilowatt	Power is measured in kilowatts
		kilogram	Refrigerant charge is measured in kilograms

- Ampere for electric current
- Kelvin for temperature
- Candela for luminous intensity
- Mole for the amount of substance

Liters are still commonly used, although they are not officially part of the SI system. One liter of water weighs 1 kilogram and takes up 1,000 cubic centimeters of space.

Derived Units

Many things cannot be measured in the base units. Derived units are measurements that require more than one measurement and some type of mathematical relationship. Area and volume are good examples because they require multiple dimensions that are multiplied by each other. Area is expressed in square meters and volume in cubic meters. Pressure is a derived unit because it measures the force applied over an area. Pressure is calculated by dividing the applied force by the area. The SI unit for pressure is the pascal, which is the force of 1 newton applied over an area of 1 square meter. Pascals are used to measure the pressure in ductwork, but they are too small a unit for measuring refrigerant pressure. Kilopascals are used when SI units are used to measure the pressure in a refrigeration system. Figure 6-16 shows a gauge

calibrated in kilopascals on the outside scale and psi on the inside scale.

Powers of 10

One of the most important innovations of the metric system was making all subdivisions powers of 10. This makes converting between prefixes as easy as moving the decimal place. For example, to convert centimeters to millimeters, just move the decimal one place to the right. A measurement of 20.4 centimeters becomes 204 millimeters. To change 20.4 centimeters to meters, move the decimal two places to the left to get 0.204 meters. The key to working with SI units is in understanding the prefixes. Some prefixes for smaller measurements are *deci-* for 1/10, *centi-* for 1/100, and *milli-* for 1/1,000. Some prefixes for larger measurements are *deca-* for 10x, *hecto-* for 100x, and *kilo-* for 1,000x. Only *milli-*, *centi-*, *kilo-*, and *mega-* are used regularly in everyday language. Table 6-3 lists the prefixes most commonly used in HVAC/R.

6.11 USING A METER STICK

SI measurements of length for common everyday use are done with a meter stick, or a metric rule (Figure 6-17). A meter is slightly longer than a yard. Meter sticks are typically marked in centimeters, with smaller millimeter lines between each centimeter line and larger lines every 10 centimeters (Figure 6-18). To take a measurement in centimeters, read the closest centimeter and count how many millimeter lines are past the nearest centimeter marking. The centimeters make up the whole number, and the millimeters go in the first place to the right of the decimal. For example, a reading of 27 centimeters and 4 millimeters would be 27.4 centimeters (Figure 6-19). To change this to millimeters, just move the decimal over one place, and 27.4 centimeters becomes 274 millimeters. To change the reading to meters, move the decimal two places to the left, and 27.4 centimeters becomes 0.274 meters.

Figure 6-18 The numbers on a meter stick are centimeters, the lines between the centimeters are millimeters.

TECH TIP

Because the meter stick is based on a decimal base 10 system instead of a fractional system, many people who have difficulty reading rulers calibrated in inches find using a meter stick considerably easier.

6.12 ESTIMATING DIMENSIONS USING COMMON BUILDING MATERIAL DIMENSIONS

Construction in the United States is still done exclusively in traditional units of feet and inches. By knowing the standard sizes of common building materials, a technician can walk into a room and give a reasonably accurate estimate of its size. Most all buildings use repetitive patterns of some basic type of construction unit.

Figure 6-20 A concrete block has face dimensions of approximately 8 in high and 16 in wide.

Concrete Blocks

The walls in a building built with concrete blocks consist of rows of concrete blocks stacked on top of one another. Since each block is essentially the same size, you can estimate the length of any wall simply by counting the number of blocks in the wall and multiplying the number of blocks times the length of each block. Concrete blocks come in many sizes, but the most common size for the face of the block is 16 inches long by 8 inches high. In reality, the actual block is a little smaller, but with the addition of mortar joints, the overall construction unit size is 8 by 16 inches (Figure 6-20).

Example: Estimate the length and height of a wall that is 39 blocks long and 12 blocks high. You could multiply 39 blocks times 16 inches per block and then divide the answer by 12 inches per foot to arrive at an answer. However, an easier way to estimate length using small units like this is to group them into larger units. Grouping the blocks in threes makes the problem much easier. Three 16-inch units equal one 48-inch unit, or 4 feet. So working the problem this way, 39 blocks would be 13 groups of three. Multiplying 13 groups times 4 feet yields a length of 52 feet. Use a similar grouping technique for the height. Since the blocks are 8 inches high, each group of three blocks takes up 2 feet ($8 \text{ inches} \times 3 = 24 \text{ inches}$). Twelve blocks high would be 4 groups of 3, and 4 groups times 2 feet per group gives a height of 8 feet. Figure 6-21 illustrates how this grouping works.

Framing

Floor joists, ceiling joists, roof rafters, and wall studs are normally spaced either 16 inches or 24 inches apart. This distance is measured center to center. The center of each framing unit is either 16 inches or 24 inches from the center of the previous framing unit. Like concrete blocks, the 16-inch framing units can be grouped by threes to form 4-foot counting units. Do not count the first stud, joist, or rafter when counting framing units because you are really

Figure 6-21 Three blocks high equals 2 ft. Three blocks long equals 4 ft.

counting the spaces between them (Figure 6-22). So a wall that has 10 studs would be counted as 9 stud spaces, or three groups.

Example: Estimate the length of a wall that has 31 studs 16 inches on center. After subtracting for the first stud, this wall would have 30 stud spaces, or 10 groups of three. The length would be 10 groups \times 4 feet = 40 feet.

Example: Estimate the length of a building that has 35 roof rafters 24 inches on center. After subtracting for the first rafter, this wall would have 34 rafter spaces. The length would be 34 spaces \times 2 feet = 68 feet.

Drop Ceilings

Drop ceilings work well for estimating room size. Ceiling tiles for drop ceilings are usually either 2 feet by 2 feet or 2 feet by 4 feet. For length: count the tiles and multiply by either 2 or 4, depending on the type of tile. For area: count the tiles and multiply by either 4 or 8, depending on the tile dimensions.

Example: Estimate the dimensions of a room with a 2 \times 2 drop ceiling that is 10 tiles wide and 15 tiles long. The dimensions are found by multiplying the number of

Figure 6-22 Because the center to center distance between studs is 16 inches, three stud spaces covers approximately 4 feet.

tiles by 2: 10 tiles \times 2 feet = 20 feet, and 15 tiles \times 2 feet = 30 feet.

Example: Estimate the area of the same room. There are two solutions. One would be to calculate the dimensions (as above) and then multiply the dimensions: 20 feet \times 30 feet = 600 square feet. Another solution would be to calculate the number of tiles and multiply by 4: 10 tiles \times 15 tiles = 150 tiles, and 150 tiles \times 4 square feet = 600 square feet.

Sheetrock, Sheathing, and Plywood

Sheetrock, sheathing, and plywood are easy to use for estimation because they all commonly are 4 feet by 8 feet. Some exterior sheathing and siding products also come in 9-foot and 10-foot lengths. Sheetrock is often run horizontally rather than vertically. When run vertically on the wall, the 4 foot width can be used for estimating distance. Count the number of pieces wide on a wall, roof, or floor and multiply by 4 to get an estimate of length.

Example: Estimate the length of a wall that is covered by 12 pieces of sheathing. Multiply 12 \times 4 feet = 48 feet in length.

UNIT 6—SUMMARY

The four physical properties measured are distance, area, volume, and weight. Compound measurements, such as density or pressure, compare more than one physical measurement. Flow measurements measure a quantity over time. Examples of flow measurements used in HVAC/R include air flow, measured in cubic feet per minute (CFM), and water flow, measured in gallons per minute (GPM). In the United States, we currently use a mix of customary units based on the inch-pound system and SI units. Distances are measured in yards, feet, and inches. Small measurements are done in fractions of an inch. Area measurements require two dimensions and are stated in square units, such as square inches. Volume measurements require three dimensions and are stated in cubic units, such as cubic feet. Everyday weight measurement is done in avoirdupois pounds and ounces, with 16 ounces in a pound. Very small weight measurement is done in grains: there are 7,000 grains in an avoirdupois pound. Silver brazing alloy is sold in troy pounds and ounces, with 12 ounces in a pound. SI measurement is the standard system for all science work and most international trade. SI measurements are all base 10, using decimals instead of fractions. Distance is measured in meters, weight in grams, and liquid volume in liters. Prefixes are used to indicate smaller or larger quantities in multiples of 10. The most common prefixes are *milli-* for 1/1,000th, *centi-* for 1/100th, and *kilo-* for 1,000. SI units can be converted from one to another just by moving the decimal. Measurements can be estimated using groupings of common construction materials. Materials with 16-inch dimensions, such as concrete blocks or wall studs, can be grouped in threes to form 4-foot groups. Materials with 24-inch dimensions, such as drop ceiling tiles, can be counted and doubled.

UNIT 7

Properties of Matter

OBJECTIVES

After completing this unit, you will be able to:

1. explain why the properties of matter are important to the HVACR field.
2. explain the law of conservation of matter and give an example.
3. discuss the unique characteristics of the three states of matter.
4. name the physical and thermal properties of matter, and tell why it is important for the HVACR worker to understand them.
5. explain the difference between weight and mass.
6. explain the importance of testing standards.
7. demonstrate how to calculate the density, specific volume, and specific gravity of a material, and discuss how this information is used.
8. identify the common temperature reference points.

7.1 INTRODUCTION

Matter is all around us; matter is what makes up the earth and everything in and on the earth. Understanding the states and properties of matter is important to the HVACR technician because all heating and cooling requires some change to matter. During both the heating and cooling process, matter may expand or contract, melt or freeze, or even appear to vanish through evaporation or combustion.

Some types of matter are easily heated or cooled, while other types of matter take more heat to get a temperature change. Different forms of matter respond differently when heated or cooled. To better understand what happens when things are heated and cooled and why it happens, you must understand matter and its properties.

Matter can be identified by its properties because each type keeps its own unique set of properties regardless of the sample size. A single drop of water reacts and responds to pressure and temperature just like an ocean of pure water would.

7.2 MATTER

Matter is anything that has mass and occupies space. Here on earth, matter may be thought of as anything that has weight and occupies space. Water and air are example of matter; light and sound are not matter. Only a limited amount of water or air can be put in a container until it is full and there is no more space inside. However, a container will not “fill up” with light or sound because they do not occupy space.

The law of conservation of matter states that we cannot create or destroy matter. Matter can change its form, but it cannot disappear. We can grind, crush, or burn matter, but it still exists in the same quantity, just in a different form. When a log burns in a fire, its matter is not destroyed; it

simply changes from one form to another. The log is mainly made up of carbon and hydrogen atoms. When it burns up in a fire, much of it is changed from a solid to a gas. The carbon and hydrogen combine with oxygen to form carbon dioxide, carbon monoxide, and water. Some unburned carbon leaves as smoke and some minerals and carbon are left as ash. If you could capture all of the products of combustion and weigh them, they would weigh the same as the wood and oxygen you started with.

7.3 THE STRUCTURE OF MATTER

Everything on earth consists of different combinations of ninety-four naturally occurring chemicals called elements. We are familiar with some elements because they are used in their pure form. For example, metals like gold, platinum, lead, mercury, iron, copper, and aluminum can be used in their pure element form. Some gases, like argon and nitrogen, are used as pure elements.

Atoms

The smallest piece of an element that can exist and still retain the same chemical properties is the atom. Atoms are made of small particles called protons, neutrons, and electrons. Protons are positively charged, electrons are negatively charged, and neutrons have no charge. Atoms have a nucleus composed of protons and neutrons. Clouds of negatively charged electrons orbit around this nucleus (Figure 7-1). However, most matter does not exist as an element but as a compound made up of more than one atom.

Molecules

The smallest part of anything that is not an element is a molecule. When the atoms of an element join together with themselves or with other types of atoms, they form

Figure 7-1 The carbon atom has six protons and six electrons.

molecules. Energy binds atoms to each other to form molecules (Figure 7-2). Because of their atomic structure, some materials have a predisposition to combine with other material. Oxygen is an example of an element that is normally only found in molecules made up of the same type of atoms. Two oxygen atoms join to form one molecule of O_2 (pronounced *O-two*), the air we breathe.

Different types of atoms can also join to form different types of matter. Water (H_2O), for example, is formed when two hydrogen ($H + H$) atoms and one oxygen (O) atom unite. The amount of energy holding the atoms together changes when they combine to form molecules. This change absorbs or releases energy. When hydrogen combines with oxygen, a large amount of heat is released. Chemical energy is the energy change that takes place when the atoms of materials rearrange themselves to form entirely new materials from the same atoms. It is important to remember that no matter or energy is “lost”; it just changes.

Figure 7-2 The methane molecule is composed of one atom of carbon and four atoms of hydrogen.

Figure 7-3 Three states of matter.

7.4 STATES OF MATTER

In air-conditioning and refrigeration work, you will encounter matter in three states: solid, liquid, and gas, as shown in Figure 7-3. The state that a substance is in depends upon its physical properties, the pressure applied to it, and its temperature. Water is an example of matter that is commonly found at standard atmospheric pressure in three states. It is a solid (ice) at 32°F (0°C), a liquid between the temperature of 32°F (0°C) and 212°F (100°C), and a vapor or gas at 212°F (100°C) and above. These three different states of matter each represent a different level of molecular energy. The energy levels from lowest to highest are solid, liquid, and gas.

7.5 SOLID

Solids have the lowest energy level of these three physical states. The molecules of a solid remain basically fixed in place. They do vibrate, but they do not move about. Solids have a definite shape and they will hold their shape under some stress. Gravitational force on solids creates downward pressure on the surface that the solids rests on. Small changes in the volume of a solid occur from temperature change. The volume increases slightly when the temperature is increased and decreases slightly when the temperature is decreased. Examples of solids are steel, bricks, rocks, ice, wood, and paper.

7.6 LIQUID

The molecules of a liquid have a higher energy level than the molecules of a solid. They move freely about while still maintaining close contact with each other. Liquids take the shape of their container and must be supported on the sides as well as the bottom. When liquid fills an open container, it exerts both a horizontal and a downward pressure on the container. This pressure is due to gravity and is the greatest at the bottom and decreases to zero on top of the surface. Examples of liquids are water, oil, gasoline, paint, alcohol, milk, honey, and mercury.

Small changes in the volume of a liquid can occur with changes in temperature. The volume increases slightly when the temperature is increased and decreases slightly when the temperature is decreased.

Figure 7-4 Pressure is exerted evenly on all surfaces in a hydraulic system.

Liquids are noncompressible, meaning their volume will not change under pressure. In a closed container that is completely filled with liquid, any pressure applied to the liquid pushes out evenly throughout the container. This is the principle behind the application of hydraulics.

Figure 7-4 shows a hydraulic system containing a liquid such as oil. The system has a small cylinder and a large cylinder connected by a pipe, with tight-fitting pistons in each cylinder. The cross-sectional area of the small piston is 1 in^2 , and the area of the large piston is 30 in^2 . A force of 1 lb when applied to the smaller piston will create a pressure of 1 psi throughout the system. This pressure will support a weight of 30 lb on the larger piston because the force of 1 psi is applied to every square inch of surface: $30 \text{ in}^2 \times 1 \text{ psi} = 30 \text{ lb}$.

7.7 GAS

The molecules of a gas have a higher energy level than the molecules of a liquid. They move freely about and avoid close contact with each other. A gas or vapor has no fixed shape or volume. Gases must be contained on all sides in a closed container or they will escape into the atmosphere. A gas fills its container space completely, and its pressure is dependant on its mass and temperature. That means that the more gas you put into the same size container, the higher

Figure 7-5 Gas exerts pressure evenly on all surfaces containing it.

the pressure. A gas exerts its pressure on its container uniformly in all directions (Figure 7-5). Examples of gases are air, steam, refrigerant, CO_2 , natural gas, and helium.

As with both solids and liquids, changes in the volume of a gas can occur with changes in temperature. The volume increases when the temperature is increased and decreases when the temperature is decreased. Unlike solids and liquids, the volume of a gas can be changed dramatically by simply reducing the size of its container. Reducing the volume of a gas by reducing the size of its container is called compression. Gases are the most variable of the three states because all of their physical characteristics can be easily manipulated.

TECH TIP

A fluid is anything that flows. Most people think of liquid as being the only fluid, but gases are also fluids. The wind blowing outside is acting as a flowing fluid, in this case air. Flowing air is much like running water in a stream—flowing air exerts force on objects. In the same way, refrigerant vapor is a fluid flowing through the system, and its inertia applies force. When it makes a turn as a result of a 90° -angle in a pipe, the inertia of the fluid is affected by the 90° -turn.

7.8 CRITICAL POINT

As a liquid-vapor mixture is heated in a closed space, the pressure and temperature of both increase. The liquid and vapor become more alike as the temperature and pressure increase. The density of the liquid decreases while the density of the gas increases. At a high enough temperature and pressure, there is no longer a distinction between liquid and vapor, and all of the substance behaves like a vapor. The temperature and pressure where the liquid state no longer exists is called the critical point. The temperature, pressure, and specific volume at the critical point are called the critical temperature, critical pressure, and critical volume.

7.9 TRIPLE POINT

The state of a substance is dependent on both the pressure and temperature. There is only one specific pressure and temperature for each substance where it can exist as a solid, liquid, and gas simultaneously in thermal equilibrium. This specific pressure and temperature is called the triple point. This means that all three states are present and they are not in the process of changing from one state to another. A slight change in either the pressure or temperature will cause one of the three states to disappear. The triple point of most substances is less than atmospheric pressure. The triple point of pure water is at 0.01°C at 7.58 mm of mercury absolute pressure, which is the same as 32.02°F at 0.09 psia . Psia measures absolute pressure—pressure above a perfect vacuum. The pressure of 0.09 psia is very small. By comparison, atmospheric pressure is 14.7 psia .

TECH TIP

Since the triple point will only occur at a very specific pressure and temperature for each substance, the triple points of several common materials are used to precisely calibrate thermometers.

7.10 PROPERTIES OF MATTER

The properties of matter can be divided into two areas: chemical properties and physical properties. A substance's chemical properties describe how it reacts to other chemicals. These properties determine whether a chemical will react with other chemicals to form new compounds and what type of compounds will be formed. Some of matter's chemical properties include heat of combustion, reactivity, and pH. Chemical properties of matter are covered as required in the appropriate units in this book.

A substance's physical properties help determine its size, shape, form, and state. Some of matter's physical properties include weight, mass, density, and thermal properties. The thermal properties of matter are particularly important because most HVACR work relates to the addition or removal of heat from matter.

7.11 WEIGHT AND MASS

Mass is a way of measuring "how much" matter an object has. The definition of *mass* is the fundamental measure of all the matter in the object as a measure of its inertia. Inertia is the tendency of things that are at rest to stay at rest and for things that are in motion to stay in motion. Items with a larger mass have more inertia than items with less mass. Heavier objects are harder to start moving than lighter objects because of their inertia. Heavier objects are also harder to stop moving once they start due to their inertia.

On earth, weight is used to measure mass because the weight of an object is proportional to its mass. The definition of *weight* is the force of gravity acting on an object. This means that objects with more mass weigh more. The weight of an object will change when the gravi-

tational forces on it change. The mass of an object does not change and is not dependent on gravity. Although the *Apollo* astronauts weighed less on the moon than they did on earth, their mass remained the same. Figure 7-6 compares the weight and mass of an astronaut on earth and on the moon.

7.12 VOLUME

Volume is a measurement of the space taken up by matter. In traditional units, this is usually cubic feet (ft³); in SI units, it is usually liters (L). The volume of a substance is not fixed; it changes with changes in temperature. In general, all matter expands when it is heated and contracts when it is cooled. The volume of a solid changes only slightly with temperature change. Liquids change more in volume than solids with temperature change, and gas volumes change a great deal with temperature change.

Solids and liquids do not change in volume with pressure changes, but gases do. A gas can be compressed into a much smaller volume or expanded into a much larger volume.

7.13 STANDARD CONDITIONS

The conditions under which a test is performed can affect the results of the test. The pressure and temperature conditions that a material is tested at can affect its volume. This will have an impact on density, specific volume, and specific gravity calculations. It is important when comparing system performance or performing calculations on material properties that the tests and calculations be done at the same conditions. Standard conditions are established by industry organizations to make it easier to compare the results of tests run by different people.

Unfortunately, since there are many types of tests and many organizations, there are many standards. It is not enough to state that you are using "standard conditions"; you need to specify whose standard you are using. For most chemistry and physics, the Standard Temperature and Pressure, or STP, is used. These were established by the International Union of Pure and Applied Chemistry in 1997 as 0°C temperature and 100 kpa (kilopascals) pressure. This translates into 32°F and 14.5 psia, or 29.5 in Hg absolute in traditional measure.

More relevant standards for air-conditioning technicians are the AHRI standard operating conditions for testing equipment. AHRI publishes many standard testing conditions for different types of equipment. The AHRI definition of *standard air* is "air weighing 0.075 lb/ft³, which approximates dry air at 70°F and at a barometric pressure of 29.92 in Hg." In SI, this translates to a density of 1.2 kg/m³, a temperature of 21°C, and at a barometric pressure of 101.3 kpa.

The most widely quoted AHRI standard is probably the "A" test condition for air-cooled air-conditioning equipment. This is 95°F outside ambient temperature, 80°F indoor dry bulb temperature, and 68°F indoor wet bulb temperature. When a company publishes the performance of their air-conditioning equipment, they typically reference this standard.

7.14 DENSITY

Density compares the weight of a substance to its volume. To find the density of something, divide its weight by its volume. In the United States, we typically use pounds for the weight and cubic feet for the volume. Thus, the density of something tells us how much it weighs per cubic foot. “Heavier” substances, such as lead, will have a high density, while “lighter” substances, such as wood, will have a low density.

A material’s density is not fixed. Since a substance’s volume changes with pressure and temperature, its density also changes with pressure and temperature. This is especially true for gas because gas volume is subject to far greater changes than either solid or liquid. Gas can be compressed, or squeezed, to a smaller volume. The amount that a solid or liquid can be squeezed is very slight. Gas also expands and contracts with temperature changes much more than either solid or liquid. Since volume can change with temperature and pressure, a reference temperature and pressure are needed when determining density. Density is meaningless without a reference temperature and pressure.

In air conditioning, one practical impact of density changes in a gas is the fact that hot air rises. Hot air is less dense than is cold air because hot air expands. This means that the same weight of air takes a greater volume. Another way to look at this is that there are fewer air molecules in the same volume, making the hot air lighter. The less dense hot air rises above the denser cooler air. This is why the temperature of the air near the ceiling is usually a few degrees warmer than the temperature of the air near the floor (Figure 7-7).

Figure 7-7 Warm air rises to the top of a room because of its lower density.

Figure 7-8 Density and specific volume.

7.15 SPECIFIC VOLUME

Specific volume is the weight of a standard unit of measure for a material. Specific volume uses the same information that density does, only backward. Specific volume compares the volume of a substance to its weight (Figure 7-8). To find the specific volume of a substance, divide its volume by its weight. Using traditional measures, specific volume tells us how much space a pound of something will take up. Like density, a specific-volume specification should have a reference temperature and pressure because a substance’s specific volume will also change with pressure and temperature.

TECH TIP

The specific volume of a refrigerant can be used to help size refrigeration compressors. The amount of refrigerant required for any particular job is determined by dividing the total amount of refrigeration needed by the refrigeration capacity of 1 lb of refrigerant. This yields the number of pounds of refrigerant the compressor must move. However, compressors are rated by the volume of gas they can move, not by the weight of refrigerant. Multiplying the refrigerant’s specific volume times the weight of refrigerant yields the volume of refrigerant the compressor must move.

7.16 SPECIFIC GRAVITY

Specific gravity is a way of relating a material’s mass and volume to a constant. It is the ratio of the density of a material to the density of a common material. Solids and liquids are compared to water; gases are compared to air. The constant used has a specific gravity value of 1 because that is always the result when any number is divided by itself.

Materials with lower specific-gravity values will float on materials with higher specific-gravity values. If a solid material has a specific gravity less than 1, it is lighter than water and it will float. If the solid has a specific gravity greater than 1, it is heavier than water and it will sink.

The same is true of gases. Natural gas is lighter than air and has a specific gravity of about 0.60, making it about 40 percent lighter than air. LP gas is heavier than air with a specific gravity of approximately 1.52, about one and a half times heavier than air. Specific gravity is called a “unitless” measurement because the units cancel out when you do the division. This is useful because a particular substance’s specific gravity will not change from one measuring system to another. If something is twice as heavy as water in “traditional” units, it will also be twice as heavy in metric units. This is not the case for either density or specific volume. The actual numbers arrived at with either density or specific volume depend very much on the units used. On the other hand, specific gravity remains the same regardless of the units used to arrive at it. It is important to compare apples to apples. If you state water’s density in pounds per cubic foot, you also must state whatever you are measuring in pounds per cubic foot.

SERVICE TIP

The specific gravity of a fuel gas is important when using pipe sizing charts. A pipe’s resistance to flow changes with the specific gravity of the gas traveling through it. Gas piping offers more resistance to gases with higher specific gravities than to gases with lower specific gravities. For this reason, gas piping charts specify the specific gravity of the gas they are designed for.

7.17 EXAMPLE CALCULATIONS

The AHRI definition of *standard air* will be used as the reference temperature and pressure for all our examples. Take the example of a gas with a weight of 4 lb and a volume of 64 ft³. To calculate density, divide 4 lb by 64 ft³ to arrive at a density of 0.0625 lb/ft³. To calculate specific volume, divide 64 ft³ by 4 lb to get a specific volume of 16 ft³/lb. You can easily convert between density and specific volume by dividing them into 1. In our above example, dividing 16 into 1 yields 0.0625, and dividing 0.0625 into 1 yields 16.

For another example, examine a solid that weighs 300 lb and takes up 3 ft³. To calculate density, divide 300 lb by 3 ft³ and arrive at a density of 100 lb/ft³. To calculate specific volume, divide 3 ft³ by 300 lb to get a specific volume of 0.01 ft³/lb. You can easily convert between density and specific volume by dividing them into 1. In our above example, dividing 0.01 into 1 yields 100; dividing 100 into 1 yields 0.01.

Notice that in each case density and specific volume are “opposites.” If something has a high density, it will have a low specific volume. Likewise, if it has a low density, it will have a high specific volume. In general, solids and liquids have high densities and low specific volumes. Gases are just the opposite; they tend to have high specific volumes and low densities.

To calculate specific gravity of a solid or liquid, divide its density by the density of water. You only need to remember to compare apples to apples. If you state water’s density in pounds per cubic foot, you also must state whatever you are measuring in pounds per cubic foot.

The density of water in traditional units is usually stated as 62.4 lb/ft³ at standard conditions. Applying this to the solid in the second example, the specific gravity of the solid would be 100 divided by 62.4, or 1.6 (rounded). This substance would be much heavier than water and would sink.

For gases, the density of the gas is compared to the density of air. The density of air at standard conditions is usually stated as 0.075 lb/ft³. The specific gravity of the gas used in the first example would be 0.0625 lb/ft³ divided by 0.075 lb/ft³, or 0.83 (rounded). This substance is lighter than air and would rise.

SI Calculations

SI calculations for density and specific volume are performed in the same way as for traditional units, just using SI units. For example, density can be calculated in kilograms per liter, while specific volume would be liters per kilogram. Take the example of a liquid with a weight of 3 kg and a volume of 4 L. To calculate density, divide 3 kg by 4 L to arrive at a density of 0.75 kg/L. To calculate specific volume, divide 4 L by 3 kg to get a specific volume of 1.3 (rounded) L/kg.

Metric units provide a shortcut when determining specific gravity. Since 1 L of water weighs 1 kg, the density of water is 1 kg/L. This means that densities calculated in kilograms per liter also represent the specific gravity. In the example above, the specific gravity of the liquid is 0.75 because it is equal to the density. This also works for the smaller units of grams and milliliters. A substance’s density in grams per milliliter is also its specific gravity.

7.18 MELTING AND FREEZING POINTS

The melting point of a material is the temperature at which the material begins to change from a solid state to a liquid state when heat is added. When a substance changes from a solid to a liquid, the potential energy of the molecules increases, but the temperature stays the same. This means that when a solid melts, the liquid being formed is the same temperature as the solid it came from.

The freezing point of a material is the temperature at which the material begins to change from a liquid state to a solid state when heat is removed. The melting point and freezing point are the same except for the direction of heat flow. If heat is flowing into the material, it is melting, and if it is flowing away from the material, it is freezing. Figure 7-9 lists a single temperature for both the melting and freezing temperature for the materials shown.

Mixtures of two or more substances can create a solution with a substantially lower freezing point than either substance alone. Ethylene glycol and water is a good example. Pure ethylene glycol, the primary component in antifreeze, freezes at around 8°F, and water freezes at 32°F. Systems exposed to cold winter temperatures easily freeze at these temperatures. But a solution of 60 percent

Figure 7-9 Melting points for several materials.

ethylene glycol and 40 percent water freezes at a much lower -48°C (Figure 7-10).

7.19 EVAPORATION

Evaporation is gradual change of state from liquid to gas that occurs when the liquid is below the boiling point. Only the molecules at the surface of the liquid can evaporate. The molecules in the liquid are in constant motion but traveling at different speeds. Liquid molecules are frequently colliding with each other. If a molecule at the surface is struck hard enough by another molecule, it may gain enough kinetic energy for it to leave the liquid and become a gas molecule even though the temperature of the liquid is below the boiling point.

Since higher temperatures mean higher average molecular speed, evaporation increases as the temperature of

the liquid increases. Increased surface area also increases evaporation because evaporation only occurs at the surface. A third factor is the concentration of the gas molecules around the liquid. Water evaporates more slowly when the air around it is at a high relative humidity.

TECH TIP

Evaporation is very important to everyday life. If water did not evaporate at temperatures below the boiling point, after mopping a floor the water would remain on the floor indefinitely.

Some liquids, like oils, do not appear to evaporate. If you spill some on the counter today it will still be there tomorrow. This is because their molecules do not strike each other hard enough or at the correct angle to eject the surface molecules from the liquid.

7.20 BOILING AND CONDENSING POINTS

Boiling describes a rapid change from a liquid state to a gaseous state. The boiling point of a liquid is the temperature at which the saturated vapor pressure of the liquid equals the surrounding atmospheric pressure. The difference between evaporation and boiling is that when a liquid is boiling, molecules are changing throughout the liquid and forming gaseous bubbles, while evaporation takes place only on the surface. Heat is required to make a substance boil. When a liquid boils, the potential energy of the molecules increases, but the temperature stays the same. This means that when water boils, the water and the steam coming off the water are both 212°F (Figure 7-11).

The condensing point is the temperature at which gaseous molecules are releasing heat and joining together to form a liquid. Condensation of a vapor occurs when the molecules of gas slow down as heat is removed. The molecules begin to clump together and form a liquid. Condensing releases the potential energy that was absorbed when the

Figure 7-10 The freezing point of water/glycol solutions changes depending on the percentage of glycol.

Figure 7-11 Both the water and the steam are 212°F .

Figure 7-12 The water in a pressure cooker boils at 257°F under a pressure of 15 psig.

molecules changed from a liquid to a gas. The difference between the boiling point and the condensing point is which direction heat is flowing.

7.21 EFFECT OF PRESSURE ON BOILING POINT AND CONDENSING POINT

The boiling and condensing points of any liquid are controlled by the pressure. Remember that the boiling point occurs when the vapor pressure of the gas bubbles in the liquid equal the pressure surrounding the liquid. When that pressure is increased, the liquid molecules have to gain more kinetic energy to reach escape velocity to become a gas. Thus, increasing the pressure on a liquid increases the boiling point.

For example, the boiling point of water at atmospheric pressure is 212°F. When the pressure on the water is increased to 15 psi above atmospheric pressure, the boiling point is increased to 257°F. This is the secret of pressure cookers. By increasing the pressure, the water in the pressure cooker heats to a temperature higher than 212°F (Figure 7-12).

This same principle is used in car radiators. The radiator cap maintains a pressure above atmospheric pressure in the engine's cooling system, effectively raising the boiling point of the engine coolant to prevent it from boiling (Figure 7-13).

A lower pressure will result in a lower boiling point. Reducing the pressure below atmospheric with a vacuum pump will lower the boiling temperature of water. Figure 7-14 shows the boiling point of water at different pressures.

The refrigerant cycle is based on changing the pressure of a liquid to change its boiling and condensing temperatures. By lowering the pressure, the boiling point of the refrigerant is lowered enough so it can boil and pick up heat at a lower temperature. Raising the pressure on the refrigerant vapor makes it possible to condense the vapor back into a liquid at a higher temperature by removing heat.

Figure 7-13 The cap on a car radiator increases the boiling point of the engine coolant by increasing the pressure in the radiator.

Figure 7-14 Pressure-temperature curve for water.

SERVICE TIP

The purpose of a vacuum pump is to ensure that the refrigeration system has no air or moisture in it before charging it with refrigerant. The low pressure created by the vacuum pump causes any water droplets in the system to boil to a gas so the water can be removed by the vacuum pump.

7.22 SUBLIMATION AND DEPOSITION

When a solid changes to the gaseous state without forming a liquid, it is called sublimation. Under some condition, molecules at the surface of the solid can change from a solid to a gas. An example of sublimation is ice that

disappears in a frost-free refrigerator. The ice has not truly disappeared; it has sublimated to a gas. The water vapor is then deposited on the evaporator as frost, changing from a gas back to a solid. When a gas changes to a solid without going through the liquid phase, that process is called deposition.

SERVICE TIP

“Freezer burn” is caused by sublimation. The water in frozen food slowly sublimates out, leaving the food dry and tough. Freezer burn can be reduced by using heavy-duty plastic wrap and containers designed to reduce the amount of water that can pass through the container.

UNIT 7—SUMMARY

Matter exists in three forms: solids, liquids, and gases. Adding heat can change a solid to a liquid and a liquid to a gas. Solids and liquids do not change size by adding increased pressure. Gases do change size with changes in pressure. An increase in pressure can increase the boiling point of a liquid, or the temperature at which a liquid turns to a gas. This is the basic principle on which all HVACR systems work.

UNIT 8

Types of Energy and Their Properties

OBJECTIVES

After completing this unit, you will be able to:

1. explain the difference between potential and kinetic energy.
2. list common forms of energy and the units used to measure them.
3. explain how the structure of molecules and atoms affects chemical and electrical energy.
4. explain the relationship among energy, work, and power.
5. calculate energy conversions using watts, BTU, foot-pounds, and joules.
6. diagram the electrical distribution system.

8.1 INTRODUCTION

At its most fundamental level, heating and air conditioning is about controlling energy. Many tasks performed by air-conditioning technicians involve controlling and measuring energy. Heating is the process of adding thermal energy; air conditioning and refrigeration are processes that remove thermal energy. Other types of energy are often used when transferring thermal energy. Understanding energy and how it affects our world is crucial to understanding heating, air conditioning, and refrigeration.

8.2 ENERGY, WORK, AND POWER

The world and everything in it can be divided into two large categories: matter and energy. On earth, matter has weight and takes up space; everything around us is made of matter. Energy affects matter, but energy has no weight and does not take up any space.

Energy acts on matter to perform work. Work is done when energy is transferred to an object. For example, the mechanical energy used to compress a spring is transferred to the spring. The spring contains more energy than it did before it was compressed. When energy is transferred into an object, the object is changed in some way. Energy makes matter move, changes its temperature, and even changes its physical state.

The relationship among energy, work, and power is typically explained using the example of a moving object. Mechanical work is defined as force multiplied by distance. A foot-pound of mechanical work is performed when 1 lb is moved a distance of 1 ft (Figure 8-1). Moving 5 lb a distance of 2 ft would represent 10 ft lb of work. This describes the amount of work done, but it does not describe how long it took. Horsepower measures the rate of mechanical work. One horsepower (hp) is a rate of work equal to 33,000 ft lb/min. Moving 33,000 lb a distance of 1 ft over the course of 1 min would require 1 hp (Figure 8-2). Therefore, 1 horsepower (hp) is a rate of work equal to 33,000 ft lb/min. The relationship among energy, work, and power can be stated as follows: energy is the ability to do work, work is the result

Figure 8-1 A foot-pound of work is moving 1 lb 1 ft.

of transferring energy, and power is the rate at which the work is accomplished.

TECH TIP

James Watt designed and sold steam engines. He needed a way to compare the output of his machines to the primary means of power being used at the time: horses. He studied the work rate of horses and developed his formula for horsepower. He determined that on average, a horse could work at a rate of 33,000 ft/lb per minute. He rated his machines by horsepower so that people buying the machines had an idea of how much work they could accomplish.

Figure 8-2 One horsepower is moving 33,000 lb 1 ft in 1 min.

8.3 POTENTIAL AND KINETIC ENERGY

Something that has potential has ability. Potential energy is energy that is stored, waiting to perform work. Something that is kinetic is in motion. Kinetic energy is energy in motion performing work. A battery is a good example of potential energy. The battery has the potential to create a flow of electrical current, but current does not flow until a circuit is created. When a path is formed, electrons flow from one pole to the other, creating a flow of electrical current. This converts some of the potential energy in the battery to kinetic energy because the electrons in the circuit are in motion. Other examples of potential energy include a compressed spring or water held in a reservoir behind a dam. Releasing the spring releases the mechanical energy by putting the spring in motion, converting potential energy to kinetic energy. Releasing water through the spillway of the dam converts the water's potential energy into kinetic energy because the water is in motion (Figure 8-3).

Potential and kinetic energy are also present at the molecular level. At temperatures above absolute zero, all molecules move or vibrate. The vibrations and movements are examples of kinetic energy because they are associated with motion. As the temperature of the molecules increases, the motion and kinetic energy also increase.

The physical state of the matter determines the molecule's potential energy. It takes energy to change the state of matter. The molecules of a liquid have less attraction for each other than the molecules of a solid. They move about freely because they have a higher level of potential energy than the molecules of a solid. Similarly, the molecules of a gas have an even higher amount of potential energy than a liquid. The energy that goes into changing the state of a substance is potential energy because it does not affect the motion of the molecules, only their positioning relative to each other. Large amounts of energy are required to change the state of a substance, but its temperature remains the same during this change of state. At the molecular level, energy that is associated with molecular motion and temperature is kinetic energy, while energy that is associated with a physical change of state is potential energy.

8.4 FORMS OF ENERGY

We all use energy hundreds of times a day while going about our daily routine. Driving a car, heating a home, operating a computer, and even playing music all use energy. Energy exists in many forms, and some common forms of energy used in heating and air conditioning are the following.

- Chemical
- Thermal (heat)
- Radiant (light)
- Electrical
- Magnetic
- Mechanical

This is by no means a complete list of energy forms, just the forms of energy most often involved in the air-conditioning trade.

8.5 CHEMICAL ENERGY

The smallest part of anything that is not an element is a molecule. Energy binds atoms to each other to form molecules (Figure 8-4). Because of their atomic structure, some materials have a predisposition to combine with other materials. The amount of energy holding atoms and molecules together changes when atoms combine with each other to form new molecules. This change absorbs or releases energy. Chemical energy is the energy change that takes place when the atoms of materials rearrange themselves to form entirely new materials from the same atoms. It is important to remember that no matter or energy is "lost"; it just changes.

One common use of chemical energy is for the generation of electricity. Batteries are an example of chemical

Figure 8-4 Methane molecule.

Figure 8-5 Batteries convert chemical energy into electrical energy.

Figure 8-6 Combustion turns chemical energy into heat energy.

energy. A chemical change in the materials of the battery creates electrical potential (Figure 8-5). Many tools use batteries, and some thermostats are operated by batteries instead of power from the system.

Burning hydrocarbons, like natural gas, is also another form of chemical energy. Large amounts of chemical energy are used to produce heat in gas-burning appliances. The carbon combines with oxygen to form carbon dioxide, and the hydrogen combines with oxygen to form water (Figure 8-6). The combustion of hydrocarbons is still the primary source of energy in the world.

8.6 THERMAL ENERGY—HEAT

All molecules are in motion. Not only are the electrons in motion as they orbit the nucleus, but the entire molecule vibrates with a random motion. Heat is the form of energy that gives molecules their motion. For the same state, more heat equals faster molecular motion, while less heat

equals slower molecular motion. Temperature increases or decreases as molecular motion increases or decreases. A change in thermal energy that results in a change in temperature is called a sensible heat change because the temperature change can be sensed. But not all changes in thermal energy result in a temperature change. Some changes result in a physical state change.

The arrangement and energy level of the molecules in a substance determine its physical state: solid, liquid, or gas. Solids are at the lower end of the energy spectrum. The molecules of a solid vibrate but remain more or less in the same spot. As their energy level increases, the temperature of the substance increases. When they reach the melting point, the molecules cannot stand still any longer and begin to freely move about. Now they are forming a liquid. As a liquid, all the molecules can move about, but they still maintain close contact with each other. As more energy is added, the molecules move about faster and faster and their temperature increases. At the boiling point, their energy level is too high to tolerate each other, and they separate from each other as much as possible. Now they are forming a gas (Figure 8-7).

Each of these state changes requires an enormous amount of energy. The energy added to a material at the

Figure 8-7 Matter can exist as a solid, liquid, or gas.

Figure 8-8 The water and ice are both 32°F.

melting point or boiling point does not result in a temperature change because all the energy is used to change the state of the substance. This is a crucial concept: when matter is changing state, its temperature remains the same. When ice melts, both the ice and the water melting from the ice are 32° (Figure 8-8). Once all the material has changed state, then the temperature can start to change.

A change in heat that results in a change in state is called latent heat, meaning hidden heat. This is because there is no temperature change accompanying the heat change. Of course, it is possible to see the steam coming off of boiling water, but it is not possible to measure a temperature difference between the water and the steam, because the boiling water and the steam are the same temperature.

Controlling thermal energy is usually the desired end result in heating and air conditioning. The end product of operating a furnace is supplying heat to the house. The end product of operating an air conditioner is removing heat from the house. Heat is also involved in the generation of

most of the world's electrical power. Chemical energy is used to make heat, the heat is used to make motion, and motion and magnetic energy are used to make electrical energy.

8.7 RADIANT ENERGY

Radiant energy is electromagnetic energy that travels in waves. Heat, light, radio waves, and x-rays are examples of radiant energy. Radiant energy is measured by its wavelength and frequency. Wavelength refers to the distance between the peaks of the waves; frequency refers to the number of complete waveforms per second. Lower frequencies have longer wavelengths; higher frequencies have shorter wavelengths. Figure 8-9 illustrates the relationship between frequency and wavelength. The electromagnetic energy spectrum extends from radio waves at the lowest energy level to gamma rays at the highest energy level.

8.8 ELECTRICAL ENERGY

Electrons are the subatomic particles whizzing around the outside of an atom. Electricity is basically the flow of electrons. It is not like pouring electrons in one end of a wire and dumping them out the other end. Rather, electricity is more like a string of dominoes. One bumps the next and the energy flows from one end to the other, but no individual domino moves very far. With electricity, an electron moving from one atom to another creates an imbalance in that atom, which causes it to reject an electron. This electron then has a similar effect on a neighboring atom. This chain reaction carries through the wire to provide an electrical current.

Electricity is the mainstay of all heating and air-conditioning systems. The controls are all electrical, and many of the systems use electricity exclusively for their power source. While it is true that hydrocarbon

Figure 8-10 Electromagnetism produced by current flowing through a conductor.

combustion powers the world, a large percentage of that heat energy is used to generate electricity.

8.9 MAGNETIC ENERGY

Magnetic energy is created by the alignment of electric charges. This occurs when all the molecules of a polar material are aligned so that the positive ends of all the molecules face the same direction in the material. This alignment gives the entire object a polarity and sets up an invisible magnetic field. Some materials, like iron, are attracted to this field. A magnetic field is also created around a wire that has an electrical current flowing through it (Figure 8-10). Conversely, moving a magnetic field past a wire will “pull” electrons in the wire in the direction of the magnetic field. This creates an electric current in the wire. This relationship between magnetic fields and electrical flow is the foundation of electrical generators and motors.

It might appear that making electricity by moving a magnet past a wire is “free” energy because it is difficult to see anything happening, but turning a generator by hand will dispel this misconception. When the generator is not connected to an operating circuit, it is relatively easy to turn. When an electric circuit with a small light is connected, the generator gets considerably harder to turn. If the light is replaced with a larger one, the difficulty increases. With a large enough electrical load, the generator becomes nearly impossible to turn. However, if the load is turned off, the generator turns easily again. This is just another illustration of the law of conservation: you cannot get energy for free!

Magnetic energy is usually not an end result but a way of transferring mechanical energy into electrical energy or electrical energy into mechanical energy. All electric motors used in air conditioning use a magnetic field to turn an electric current into mechanical energy. Many controls that operate motors also rely on magnetism to turn electrical energy into mechanical energy. Although magnetic energy is seldom the end result, it has a part in nearly all electrical generation.

8.10 SOURCES OF ENERGY

We depend on a variety of energy sources to maintain the lifestyle enjoyed by people in the United States. Many of the energy sources we currently use cannot be replenished; after we use them up, they are gone. These are called nonrenewable energy sources. Other energy sources can be replenished, and so they are called renewable energy sources.

Figure 8-11 Non-renewable energy sources (a) Coal cars (Courtesy of Indiana Office of Energy) (b) Uranium mining in the Navajo Nation (Courtesy of Sprol.com) (c) Drilling for petroleum based energy (Courtesy of OSHA)

TECH TIP

Conservation of the limited supply of nonrenewable natural resources is important. There is a great deal of interest by citizens' groups and the government behind the HVACR industry's push for higher efficiency equipment. Heating and air conditioning accounts for approximately 50 percent of the energy used in most homes. Selling, properly installing, and properly servicing high-efficiency equipment is good for the environment. Properly working high-efficiency equipment will result in our using less of these valuable nonrenewable sources of energy. Properly working high-efficiency equipment is also good for customers, because their utility bills will be lower as a result of consuming less energy.

Nonrenewable Energy Sources

Nonrenewable energy sources have a limited supply. Currently, most of the world's energy is supplied by nonrenewable energy sources. Oil, natural gas, coal, and uranium are examples of nonrenewable energy sources (Figure 8-11).

Crude oil is recovered from wells (Figure 8-12) and distilled into a large number of hydrocarbon fuels, including fuel oil and gasoline. These refined products are used for heating, electricity generation, and transportation.

Natural gas also comes from wells in the ground. Gas is frequently found on top of oil reserves. Like oil, natural gas is a hydrocarbon. In years past, when natural gas was encountered during petroleum exploration, the gas was burned off to allow the petroleum companies to get to the oil. Today the gas is considered as valuable as the oil. It is collected, refined, and distributed nationally through pipelines for heating and electrical generation. Gas is the cleanest burning of all the carbon-based fuels.

Coal is essentially carbon. It must be mined by digging it out of the ground (Figure 8-13). Coal is still plentiful in the United States, but many problems come with increased coal use. Coal is the dirtiest burning of the carbon fuels. The sulfur content in coal contributes to acid rain. Like all carbon-based fuels, coal produces carbon dioxide when burned. However, since coal is nearly all carbon, it produces more carbon dioxide than either gas or oil. Because the United States has such large coal reserves,

Figure 8-12 Oil well cross-section. (Source: California Department of Conservation)

many studies are underway to find cleaner uses of coal. The primary use for coal today is generating electricity.

Uranium is a radioactive element used today in nuclear power plants. It is possible to split uranium atoms to form two smaller atoms and release vast amounts of energy. The energy released from the fission, or splitting, of the uranium atom is used to heat water to steam to generate electricity. Nuclear power holds great promise, but public support has weakened because of the concern

Figure 8-13 Surface coal mine. (abutyryn/Shutterstock.com)

for safety. This is because there is a great potential for catastrophe, as was demonstrated at Chernobyl in Russia and during the 2011 earthquake in Japan, both of which caused nuclear emergencies. Another concern with nuclear power is managing the radioactive material left over from operating the plant.

The world's growing energy demands have strained the current methods of retrieving and distributing these nonrenewable resources. The increasing energy demands of the world cannot be supported indefinitely, as we are using up finite sources of energy at an ever-increasing rate.

Renewable Energy Sources

Renewable energy sources can be replenished. Interest in renewable energy sources is increasing as researchers look for long-term solutions to the world's energy appetite. Some of the renewable energy sources that have been explored include solar, wind, hydro, ocean, geothermal, and biomass.

Solar energy can be used to generate electricity using photovoltaic cells, or it can be converted into thermal energy for heating water and buildings. A few large-scale solar-generating stations have been constructed in the southwestern United States that generate electrical power and distribute it over the existing electrical grid (Figure 8-14).

Wind energy is primarily used to generate electricity. Wind generators are in use from small windmills to generate electricity in homes to large-scale projects that harvest wind power with hundreds of large, strategically placed windmills (Figure 8-15).

Figure 8-15 Wind farms use multiple large wind turbines to generate electrical power. (Stephen Bures/Shutterstock.com)

Hydroelectric power has been used for years. Projects like the Tennessee Valley Authority (TVA) have sought to turn the raw power of large rivers into electricity. However, the potential is somewhat limited, and environmental concerns have been raised regarding the drastic changes in the ecosystem that a large-scale hydroelectric plant brings. Even in the TVA, one of the world's most ambitious uses of hydroelectric power, only 10 percent of the electricity is generated by hydroelectric power.

Ocean energy can be harnessed from the waves or from the rising and falling tide. The wave motion has been used to turn generators. The tidal change can be used in coastal areas that have a high degree of tidal change between high and low tide. Gates are constructed that control the flow of sea water into and out of large areas, trapping water at high tide. The water is then released through a turbine to generate electricity.

Geothermal energy is heat from inside the earth. Hot water and steam flowing out of the ground can provide heat in areas with active thermal springs or geysers. Geothermal heat pumps can extract heat from the ground, even at relatively low temperatures. A geothermal heat pump can move three times as much heat as it consumes.

Biomass energy refers to energy derived from plants and animals. This can be as simple as burning plants for heat or as complex as converting garbage into gas and oil. Decaying trash, plants, animals, and animal wastes can be used to produce methane, the main component of natural gas. Plant and animal materials can also be used to produce fuels like biodiesel or ethanol.

8.11 ENERGY CONVERSION

Energy can be converted from one form to another. The purpose of an electrical power plant is to convert existing forms of potential energy, such as coal or natural gas, into electrical energy. (Figure 8-16) shows a modern electrical power plant. The energy conversions required to operate an air conditioner include the following:

1. Coal or natural gas is burned at the generating plant to produce steam, converting chemical energy into thermal energy.
2. The steam is used to turn a turbine, converting thermal energy into mechanical energy.
3. The turbine turns a generator, converting mechanical and magnetic energy into electrical energy.
4. The electricity is used to operate electric motors, turning electric energy into magnetic energy.
5. The electric motors use the spinning magnetic field to turn the compressor and fans, converting magnetic energy into mechanical energy.
6. The mechanical energy is used to transfer thermal energy, heat, from where it is not wanted to where it is unobjectionable.

Note that the whole process began by turning some matter, coal and oxygen, into other forms of matter, water and carbon dioxide. When hydrocarbons are burned, the carbon is combined with oxygen to form carbon dioxide, while the hydrogen is combined with oxygen to form water. The coal does not disappear; it is changed into carbon dioxide gas and water vapor. When the entire process is through, there is just as much matter as before. Also, there is just as much energy as before; it is just converted into heat.

Figure 8-16 Diagram of a coal-fired electric-generating plant.

These conversions are not perfect. Some energy is “lost” with each conversion. But energy is not really “lost.” Some of it is not directed toward the desired outcome. When the coal is burned, some of the heat leaves with the hot combustion gases. This energy is not lost in the sense that it no longer exists. It still exists, but some of the heat energy was not captured when it was converted. Likewise, all the heat energy that is captured is not used to turn the turbine; there is still a considerable amount of energy in the steam after it has passed through the turbine. Once again, all the energy was not completely captured, but the “missed” energy still exists. In virtually any energy conversion there is “lost” energy. However, it is important to understand that when energy is “lost” it does not disappear; it just does not go where it is supposed to go.

Common Energy Conversions

It would be accurate to say that the modern lifestyle we enjoy depends upon energy conversions taking place all around us that we take for granted. Operating any appliance, heating and cooling our homes, and transporting people and goods all depend upon energy conversion. Even enjoying your favorite music on your MP3 player requires converting chemical energy into electrical energy to operate, converting that electrical energy into magnetic energy to drive a speaker or headset, converting that magnetic energy into mechanical energy to make the speaker cone move, and finally converting the mechanical movement of the speaker into sound energy so that it can be heard. Some common energy conversions are shown in Figure 8-17.

Energy Conversion Is Reversible

Not only can energy be converted from one form to another, but the conversion can be reversed. A car battery is a good example of a practical use for reversible energy conversion. A car battery is basically a tank full of acid with two different types of metal plates dipped in the acid. The

chemical reaction between the acid and one set of metal plates produces an excess of electrons on the metal plate. The reaction between the acid and the other set of metal plates produces a lack of electrons. When an electrical circuit is connected between the two plates, electrons run from the plate with an electron surplus to the plate with an electron deficit, providing electricity. This is a chemical-to-electrical conversion. As electricity is used, the chemicals that supply this reaction are changed. This is how a battery is “used up.” The chemicals that react to provide the electron difference are changed to chemicals that do not support this chemical reaction. If an electrical current is applied across the set of metal plates, the chemical reaction is reversed and the chemicals are restored to their original state. This is how a battery is recharged. Most energy conversions are reversible.

Conversion Formulas

The most common energy-conversion calculations are electricity to heat and electricity to mechanical energy. Table 8-1 lists the formulas for some of the most common energy and power conversions.

For example, a 5 kW electric heater can produce 17,050 BTU of heat if operated for an hour: $5,000 \text{ W} \times 3.41 \text{ BTU/W} = 17,050 \text{ BTU}$. A 3 hp electric motor will produce the equivalent of 2,238 W of work: $3 \text{ hp} \times 746 \text{ W/hp} = 2,238 \text{ W}$. If the motor is 75 percent efficient, it will consume 2,984 W to produce 3 hp of work: $2,238 \text{ W}/0.75 = 2,984 \text{ W}$.

8.12 ENERGY CONSERVATION

The subject of energy conversion brings up an important concept in dealing with matter and energy: matter and energy cannot be created or destroyed. This is the first law of thermodynamics, often referred to as the law of conservation. It is not possible to increase the amount of heat somewhere by “making heat.” It is necessary to convert another form of energy into heat or move heat from somewhere else to where it is needed. Likewise, it is not possible to simply “destroy” the heat to reduce the amount of heat somewhere. It is necessary to convert the heat to another form of energy or move it somewhere else.

The operation of an electric heater is an example of how the law of conservation works. The heat produced by the heater represents the same amount of energy as the electricity used to produce the heat.

8.13 ENERGY DISTRIBUTION

Most of the energy we use is produced in a central location and distributed throughout the country. The two forms of energy used most in heating and cooling are electricity and natural gas.

Electrical Distribution

The laws of physics work against distributing large amounts of electrical power over long distances. According to Ohm’s law, the voltage lost through a conductor will equal the resistance of that conductor multiplied by the current traveling through the wire. Power lines have resistance. The longer the wire is, the higher its electrical resistance. To reduce the loss through the line it is necessary to reduce the current traveling through it. Power-distribution systems accomplish this by using high voltages. Electrical work, measured in watts, is a product of volts times amps. A comparison of two 1-kW electrical systems can illustrate the point (Table 8-2).

Note that the higher voltage in Table 8-2 delivers 99.5 percent of the original power while the lower voltage loses half of its power through the wire.

In practice, the voltage is changed to a very high voltage for transmission over long distances and then lowered to a safer

level for use. Alternating current is used for our power distribution because it is much easier and cheaper to accomplish the required voltage changes. The voltage is changed, or transformed, through a device called a transformer. Transformers can either increase or decrease voltage. The steps taken from the plant to your house are shown in Figure 8-18.

1. Electricity is generated at a high voltage: 20,000–33,000 V.
2. It is transformed to a higher voltage: 69,000–500,000 V.

3. It is transmitted long distances at this voltage.
4. It is transformed to subtransmission voltages at a substation: 34,500–69,000 V.
5. It is transmitted to regional substations at this voltage.
6. The voltage is transformed to a distribution voltage: 4,800–13,800 V.
7. It is distributed to pole transformers.
8. The pole transformer drops the voltage to the end user: 120–240 V.

Natural Gas

Natural gas is collected, refined, and distributed through a nationwide network of pipelines. Figure 8-19 shows a map of the major gas pipelines in the United States. Compressors are used to reduce the volume and raise the pressure of the gas in the large interstate pipelines. These large interstate pipelines typically have a 16–48-in diameter and operate at pressures ranging from 200 to 1,500 psig. Compressor stations (Figure 8-20) are located at 40- to 100-mi intervals along the pipeline to maintain the pipeline pressure. Lateral pipelines deliver the gas from the main pipelines to local distribution networks.

While large gas consumers like electric utilities and industrial plants may get their gas directly from the main pipeline, most users rely on local distribution networks. The gas pressure is reduced before entering the local distribution system. Line pressure may be as low as 3 psig because of the reduced volume of gas. Compressor stations may still be required for large local distribution systems, but they are much smaller than the stations used in the interstate pipelines. Finally, the gas passes through a regulator at each customer's location, and its pressure is reduced to very low pressures. Delivery pressure for residential natural gas is typically 6 inches water column. The cost of building and maintaining these local distribution networks represents almost half of the price of natural gas to residential consumers.

8.14 STANDARD AND SI UNITS OF WORK

Mechanical Work—Traditional Units

Mechanical work is measured by the weight of an object and how far the object is moved. In traditional English units,

Figure 8-20 Typical natural gas compressor system.

this is foot-pounds. A foot-pound is the product of multiplying the weight in pounds times the distance in feet. Moving a 50-lb weight a distance of 2 ft requires $2 \text{ ft} \times 50 \text{ lb} = 100 \text{ ft lb}$ of mechanical work. The torque wrench is commonly used in many mechanical fields to measure the mechanical force used when tightening bolts. Standard torque wrenches are calibrated in foot-pounds (Figure 8-21). The United States is one of the few countries still using traditional (standard) units of weight and measure.

Mechanical Work—SI Units

Mechanical force in the SI system is measured in newton (N) meters. This is the force of 1 N times the distance of 1 m. Metric torque wrenches are calibrated in newton meters (see Figure 8-21).

Thermal Work

When asked for a measurement of heat, most people respond with a temperature. In fact, they are partly correct. Temperature is a measure of the concentration of heat. But if a quantity is needed, temperature will not work. Temperature is a comparative measurement; it compares the concentration, or level, of heat against known standards. It does not measure the amount of heat energy in a

Figure 8-21 Torque wrench calibrated in foot-pounds in black and newton meters in red.

substance. There is a difference between heat intensity and heat quantity and how each is measured. Heat intensity describes how concentrated heat is. Heat quantity describes the amount of heat in something.

Thermal work is measured in British thermal units (BTUs), calories, or joules (Figure 8-22). The definitions for both BTUs and calories are similar. A BTU is the amount of heat required to raise 1 lb of water 1°F. A calorie is the amount of heat required to raise 1 g of water 1°C.

None of these units of heat can be directly measured; they all require calculation. Calculating the amount of heat transferred in water is easy because both BTUs and calories are defined by a temperature change in water. The formulas below show how to calculate heat quantity based on the temperature change of water.

$$\begin{aligned} \text{BTU} &= (\text{water temp difference in } ^\circ\text{F}) \\ &\times (\text{water weight in pounds}) \\ \text{calories} &= (\text{water temperature difference in } ^\circ\text{C}) \\ &\times (\text{water weight in grams}) \end{aligned}$$

Figure 8-22 (a) 1 BTU raises the temperature of 1 lb of water 1°F; (b) 1 calorie of heat raises 1 g of water 1°C.

Both BTUs and calories represent relatively small amounts of heat. One BTU is roughly equivalent to the heat given off by a single wooden kitchen match. A calorie is even smaller: it takes approximately 250 cal to equal 1 BTU! Larger units of heat quantity have been derived for many real-world applications.

In the United States we use the therm to count very large quantities of heat. A therm is equal to 100,000 BTU. Natural gas is sold by the therm. For metric heat measurement, the kilocalorie (kcal) is used. The kilocalorie is equivalent to 1,000 cal. Frequently kilocalories are referred to as Calories. The capital C differentiates the large Calorie from the small calorie. So 1,000 calories equals 1 Calorie.

TECH TIP

Kilocalories, Calories with a capital C, are the same Calories people watch when they are dieting! The phrase “burning Calories” is actually quite accurate. Your body is oxidizing the energy stores and converting chemical energy into heat energy.

Electrical Work

Since electricity is the flow of electrons, a logical unit of electricity would measure the flow of electrons. This unit is the ampere, abbreviated amp or A as a unit. One amp is a flow of 1 coulomb in 1 second. But electron flow is only part of the picture. There must be a difference in electrical charge from one side of the circuit to the other before current will flow. This difference is called potential difference and is measured in volts. A volt is defined as the potential difference across a conductor when a flow of 1 Ampere dissipates 1 Watt of electrical power. The watt is the unit used to measure the rate of electrical work.

TECH TIP

A coulomb is the SI unit of electric charge. This amounts to a quantity of 6.2415×10^{18} electrons. The ampere was originally a derived unit, based on the coulomb with the coulomb being the original SI base electrical unit. The ampere was named the SI base electrical unit in 1960. The ampere is a commonly used unit in air-conditioning work.

Since the ampere is a rate and not a quantity, the watt is also a rate. To measure the quantity of electrical work, it is necessary to state how long work is being done at the rate of 1 Watt. The watt-hour is the amount of electrical work done at the rate of 1 W for 1 hr. Watt-hours is the product of watts and hours. Operating a 100-W light for a period of 2 h requires $100 \text{ W} \times 2 \text{ h} = 200 \text{ Wh}$.

In practical terms, the watt-hour is a relatively small unit. Power companies use kilowatt-hours to measure the amount of electrical work used during the month. Figure 8-23 shows a typical kilowatt-hour meter. This is calculated by measuring the kilowatt use over time. It can be expressed using the formula $V \times A \times 0.001 \times \text{hr} = \text{kWh}$.

Figure 8-23 Typical kilowatt hour meter.

Operating ten 100-W lightbulbs for 1 hr would require $10 \times 100 \text{ W} \times 1 \text{ hr} \times 0.001 = 1 \text{ kWh}$.

Why is something with “hour” in its name a quantity and not a rate? Remember that amperes is a rate of electron flow. The “hour” in *kilowatt-hour* makes the kWh a quantity by giving a specific amount of time to work at that rate. A comparison with water would be to specify the amount of water pumped at a rate of 5 gal/min (GPM) for the period of 1 hr. The 5-GPM measure just tells the rate of water flow but does not tell how much water is pumped altogether. By specifying a time, the total quantity of water pumped can be determined to be 300 gal: $5 \text{ GPM} \times 60 \text{ min}$.

Joules—SI Unit of Energy

One problem with units of measurement based on the temperature change of water is that the specific heat of water changes slightly as its temperature changes. So the amount of heat represented by a temperature change in water depends

upon the starting temperature. This has led to the development of many different definitions of both calories and BTUs, each based on a different starting temperature and representing a slightly different heat value. For this reason, joules have replaced calories in SI measurements of thermal energy.

Joules are a heat equivalent for mechanical energy but are used today in the SI system for all forms of energy. One joule is the work done by a force of 1 Newton moving an object 1 meter. Consuming electrical power at the rate of 1 W for 1 s is the electrical equivalent of 1 joule. Today, the joule represents the standard SI measurement of energy for all types of energy.

8.15 STANDARD AND SI UNITS OF POWER

Most of the terms used to describe the capacity of air-conditioning systems and components are rate measurements. Rate measurements always measure a quantity over time. Power is a measure of the rate of work; it measures a quantity of work over time. Although any form of energy can produce power, in air conditioning the three primary types of power measured are mechanical power, thermal power, and electrical power.

Mechanical Power

Horsepower is a rate of doing mechanical work. Like foot-pounds, horsepower involves distance and weight. Unlike foot-pounds, horsepower also uses a time component because it is a rate, not a quantity. One horsepower is defined as producing 33,000 ft lb of mechanical work in 1 min. Horsepower is literally supposed to be the amount of work a horse can do, as shown earlier in the unit in Figure 8-2. Motors are still rated by this somewhat archaic term. For electric motors, 1 hp is defined as 746 W. This does not mean that a 1-hp motor consumes 746 W; it means that the mechanical work performed by the motor is equivalent to the electrical work rate of 746 W. An electric motor consumes more than 746 W per hp because electric motors are not 100 percent efficient.

Thermal Power

A very common rate used to specify the capacity of heating and cooling systems is BTU per hour. A heating system with a rating of 40,000 BTU/hr would provide 40,000 BTU of heat energy for every hour of operation (Figure 8-24). A common rating for refrigeration equipment is the ton. A ton

of cooling is defined as the amount of cooling accomplished by melting a ton of ice over a 24-hr period. Notice that this specifies both a quantity, the cooling done by 1 ton of ice, and a time, 24 hr. This quantity of cooling is 288,000 BTU because it takes 144 BTU to melt 1 lb of ice: $144 \text{ BTU} \times 2,000 \text{ lb} = 288,000 \text{ BTU}$. This time period is not usually the most convenient. Dividing both the quantity and time by 24 gives an hourly rate of 12,000 BTU/hr. This is what is more commonly thought of as a ton. Do not forget the per-hour part. A ton is not 12,000 BTU but 12,000 BTU/hr. A ton can also be stated as 200 BTU/min: 12,000 divided by 60. All three of these rates are identical; the only difference is whether you prefer to measure by the minute, the hour, or the day.

Electrical Power

The ability of electricity to do work depends on two factors: voltage and current. Voltage is a measure of the potential difference. Potential difference provides the electrical pressure, which makes current flow possible. Without a difference in voltage from one end of the wire to the other, there will be no current flow. Watts is a measure of the rate at which electrical work is done. Wattage depends upon both voltage and current. A watt is defined as 1 A of current flowing at a potential difference of 1 V. Wattage can be calculated using the formula $V \times A = W$. Wattage measures the rate at which work is accomplished. Wattage is a rate because it is calculated using amps, a measure of electrical current flow. Flows are always measured as a rate.

Wattage is a reasonable measure for small appliances and lightbulbs but for jobs like heating a house—something is needed that works better for large measurement. Kilowatts, abbreviated kW, are used to specify the energy use of heating and air-conditioning equipment. A kilowatt is equal to 1,000 W. The formula is simply $W/1,000 = kW$.

Watts—SI Unit of Power

Although the watt was originally conceived as a unit of electrical power, it is used today as the standard SI unit of power for all types of power. The watt is a rate of power equal to 1 joule of energy per second. In SI measurement systems, watts are used to measure the output of engines, electric motors, and furnaces.

8.16 ENERGY-EFFICIENCY MEASUREMENTS

A rating called the energy efficiency ratio (EER) is used to compare the efficiency of air-conditioning units. The EER is the number of cooling BTUs per hour a unit produces for every watt of electricity it uses. It is determined by dividing a unit's cooling capacity in BTUs per hour by the energy use in watts. The higher a system's EER is, the more efficient it is. The EER is calculated at the AHRI standard rating condition. The seasonal energy efficiency ratio (SEER) is adjusted for operation through a cooling season. It also represents the number of cooling BTUs per hour a unit produces for every watt of electricity it uses, but at conditions adjusted to represent an entire cooling season. A unit's SEER is normally higher than its EER.

UNIT 8—SUMMARY

Heating, air conditioning, and refrigeration are about controlling energy. Energy that is stored is called potential energy, while energy that is in use is called kinetic energy. There are many forms of energy, including chemical, thermal, radiant, electrical, magnetic, and mechanical. Energy can be converted from one form to another, but it cannot be created or destroyed. There is a definite relationship among energy, work, and power. Energy is the ability to do work, work is the amount of energy transferred, and power is the rate of energy transfer. The difference between work and power is that work is a quantity while power is a rate.

UNIT 8—REVIEW QUESTIONS

- List the forms of energy used in the heating, air-conditioning, and refrigeration industry.
- What units are used to measure heat quantity?
- What units are used to measure heat intensity?
- Explain the relationship among energy, work, and power.
- How many BTUs will a 5-kW heater produce if operated for 1 hr?
- How many BTUs are required to raise the temperature of 15 lb of water from 100°F to 120°F?
- A heat-transfer process results in 20 kcal of heat being absorbed by 1 L (1 kg) of water. What temperature will the water be if it started at a temperature of 25°C?
- Describe chemical energy, and give an example.
- How much mechanical force is required to lift a 250-lb compressor 2 ft?
- What energy unit is used today in the SI system for all forms of energy?
- How many joules of heat does a 100-W heater produce if it is operated for 5 min?
- Use a block diagram to outline a common electrical-distribution system from the power plant to your house.

- What is the required input in watts to operate an 80-percent efficient 5-hp electric motor?
- Explain the units used to measure torque.

UNIT 9

Temperature Measurement and Conversion

OBJECTIVES

After completing this unit, you will be able to:

1. define *temperature* and explain the effect it has on a substance.
2. discuss the concept of absolute zero.
3. compare various temperature-measuring devices.
4. explain the concept of absolute temperature scales.
5. explain the four types of temperature scales: Fahrenheit, Celsius, Rankine, and Kelvin.
6. demonstrate how to convert temperature from one scale to another.

9.1 INTRODUCTION

Temperature control is the primary function of most air-conditioning and refrigeration systems. Temperature measurements are among the most important measurements an air-conditioning technician will make. Taking accurate temperature readings is crucial in analyzing system performance; incorrect readings can lead to incorrect system diagnosis. This unit discusses what temperature is, the different methods of measuring temperature, and how to take accurate temperature readings.

9.2 WHAT IS TEMPERATURE?

Temperature is the measure of the average kinetic energy in a substance. Kinetic energy makes molecules move: the molecules of solids vibrate in place; the molecules of liquids and gases move about. All the molecules are not moving at exactly the same speed, and this is why temperature is defined as a measure of the average kinetic energy of a substance. The higher the temperature, the faster the molecules move. The lower the temperature, the slower the molecules move (Figure 9-1).

Temperature does not measure the amount of heat in a substance, because molecules have both potential and kinetic energy. Temperature can only measure kinetic energy; it cannot measure potential energy. A 40°F gas will have more heat in it than a 100°F liquid because the gas has a much higher potential energy than the liquid.

9.3 TEMPERATURE AND RADIANT ENERGY

Solids both absorb and emit radiant energy. They emit radiant energy at any temperature above absolute zero. The frequency of the radiant energy wave increases as the temperature increases. At around 1,000°F, the radiant energy is in the red spectrum of visible light and the object glows a dull red. As the temperature increases, the frequency of the light increases, producing shifts in the color of the visible light emitted by the solid. Figure 9-2 shows the visible light spectrum associated with different temperatures.

Below 1,000°F, materials are not hot enough to produce visible light. They still produce radiant energy but at a lower frequency. This unseen light is called infrared light because it has a wavelength that is longer than red light.

Figure 9-1 Above 1,000°F, the vibrations are fast enough to begin emitting a dull red visible light. As the temperature continues to rise, the color of the light changes. When it is very hot, it glows white.

Figure 9-2 As the temperature rises above absolute zero, the molecules begin to vibrate. The hotter the material, the faster the vibrations.

This is the light that an infrared thermometer sees when reading the temperature of a material's surface from several feet away. As the temperature increases, the color of the object changes because the wavelength of the radiation it is emitting gets shorter and shorter.

9.4 EARLY THERMOMETERS

Scientists have been devising methods of measuring temperature for nearly two thousand years. In the first century, Hero of Alexandria published his studies on pneumatics in which he described a tube with the top closed and the bottom open. The bottom is submerged in a container of water and the tube is filled with air at the top and water at the bottom. When the air that is trapped in the top of the tube was heated, the expanded air would push the water down the tube. When the air cooled, the air would contract and water would rise in the tube. This made a sort of backwards thermometer (Figure 9-3). Later, in the eleventh century, Abu Ali ibn Sina developed air thermometers based on this same principle. In the early seventeenth century, Galileo experimented with a device called a thermoscope (Figure 9-4). It consisted of a column of liquid with several glass balls partially filled with water to give them different densities. The density of the fluid they were immersed in changed with

Figure 9-3 The volume of the trapped air changes with temperature, changing the level of the water.

temperature, causing them to rise or fall. The position of the glass balls indicated the relative temperature.

All of these early instruments were affected by atmospheric pressure changes as well as temperature changes. In 1654, Ferdinando II de Medici made the first modern-style thermometer that was not affected by changes in atmospheric pressure. His thermometer used sealed tubes that were partially filled with alcohol. Many scientists experimented with different styles of thermometers using different liquids. Unfortunately, each thermometer and scale was unique, and no accepted standard existed. In 1724, Daniel Fahrenheit began producing thermometers that used mercury. Mercury's large coefficient of expansion allowed a scale with a wider range and greater precision than previous thermometers. The superiority of Fahrenheit's thermometer led to its wide adoption, resulting in the Fahrenheit temperature scale becoming the first widely used temperature scale.

9.5 GLASS-STEM THERMOMETERS

Glass-stem thermometers are still used today. An advantage of glass-stem thermometers is that they are highly reliable because they rely on properties of physics, not on a mechanical or electronic device. The temperature is measured on a scale as compared to the tip of the expanding or contracting liquid inside the thin tube. When the liquid is heated,

Figure 9-5 Glass-stem thermometer.

it expands and pushes farther up the glass tube. When it is cooled, it contracts, and the liquid level falls. Any liquid can be used, but mercury or alcohol are the most commonly used liquids. Mercury looks metallic in color, and alcohol is usually dyed red (Figure 9-5). The thinner the size of the hollow glass tube, the greater the movement per degree of temperature change. Longer, more accurate models for laboratory work are available, as are pocket sizes. Breakage is a problem, since glass thermometers are fragile.

9.6 DIAL THERMOMETERS

Dial thermometers indicate temperature by a pointer moving over a circular scale (Figure 9-6). The pointer moves because it is attached to a bimetal spring. The spring may be wound into a spiral or twisted. A bimetal is made by joining together two metals with different rates of expansion. When the bimetal is heated, one metal expands more than the other and the bimetal spring opens; when it is cooled, the spring tightens. This creates a turning motion that is used to move the pointer on the thermometer.

An advantage of dial thermometers is that they are more rugged than glass-stem thermometers and can be used for a wide variety of applications. They are also relatively inexpensive. Service technicians have used dial-type pocket thermometers for years. Figure 9-7 shows a typical dial-type pocket thermometer. The disadvantage of dial thermometers is that they are not very accurate compared to other types of thermometers.

Figure 9-6 Each increment on this dial thermometer represents 2°F—this thermometer is reading 84°F.

Figure 9-7 Analog pocket thermometer.

Figure 9-8 (a) Infrared thermometer; (b) infrared thermometer with a temperature contact probe.

9.7 INFRARED THERMOMETERS

Infrared thermometers can “see” the temperature of a surface from a distance (Figure 9-8). What they are seeing is the color of the invisible infrared (IR) light given off by the object. A detector is located inside the instrument that senses the infrared light waves. A change in the IR light’s color occurs as a result of temperature changes, which results in a change in the electrical output of the detector. A small integrated circuit converts that electrical output into a displayed temperature. The distance the detector is from the object, the surface color, and its reflectivity all affect the accuracy of the temperature reading. The most accurate reading is obtained when the object whose temperature is being read is a black, dull surface. IR thermometers are generally not useful for measuring air, liquids, shiny metal objects, or small objects.

One difference between different IR thermometers is their distance to spot ratio. This ratio tells how large the target area is compared to the distance (Figure 9-9). An instrument with a 10 to 1 ratio will measure an area of 1 in diameter when the target is 10 in away. Inexpensive tools have ratios of 4:1, while more expensive models have ratios of 12:1. More expensive models also have adjustable emissivity, so that they can be used on different surfaces.

Not all HVACR field work requires extreme accuracy. Technicians are often looking for trends in temperature change. For example, during an air-balancing job in a

Figure 9-9 Distance to spot ratio.

residence, the technician may need to know if the air coming out of the duct is colder or warmer than it was before the dampers were adjusted.

SERVICE TIP

A disadvantage of IR thermometers is that they cannot detect air temperatures; however, they can detect the temperature of the grille or register that the air is passing through. To obtain the most accurate estimate of the actual duct air temperature, point the detector into the louvers so it is pointed at the inside of the duct boot. Some IR thermometers have a laser pointer to make this easier. Move the instrument around and watch the temperature display. Watch for the highest or lowest temperature (highest for heating and lowest for AC) indicated on the display. That temperature is going to be the closest to the actual air temperature. Practice will help develop your skill in obtaining accurate temperature readings with an IR thermometer.

There are many advantages to using infrared thermometers. The fact that a temperature reading can be made from a distance may mean that you do not need to climb a ladder to get air duct readings. It may also mean that you can get a reading from the back of a hard-to-reach space. The temperature is displayed instantaneously, which speeds up your work.

9.8 DIGITAL THERMOMETERS

Digital thermometers with compact sensing elements are popular due to their speed in sensing a change in temperature and the ease in reading the alphanumeric display instead of a dial or a scale. Figure 9-10 shows a digital pocket

Figure 9-10 Digital pocket thermometer.

thermometer. Most digital thermometers require batteries or a source of electrical power to produce the digital display.

Digital thermometers can perform many functions that analog instruments cannot. These include recording temperature differences between two or more sensing elements, remembering the highest and lowest temperatures from several readings, and averaging the temperature of several readings. The display on most digital thermometers can easily be changed to show the temperature reading as Fahrenheit or Celsius.

9.9 ELECTRONIC TEMPERATURE SENSORS

Digital thermometers use three different types of temperature sensors: wire-wound elements, thermistors, or thermocouples.

Wire-Wound Sensors

A wire-wound temperature sensor changes resistance with temperature change. The resistance of most conductors increases with an increase in temperature. Normally this change is very small. This resistance change can be magnified by winding many turns of small-diameter wire into a coil that is used as a sensor. Wire-wound sensors are very accurate, but they are also the most expensive of the three types of electronic sensors.

Thermistors

A thermistor is a semiconductor that changes resistance with temperature. Thermistors are inexpensive and fairly rugged, but they are the least accurate of the three types of digital temperature measurement because their resistance change is not linear. Thermistors are frequently used as temperature-sensing devices on air-conditioning equipment. Figure 9-11 shows a thermistor used to measure the outdoor coil temperature on a heat pump.

Thermocouples

Thermocouple temperature sensors can be used to detect temperatures that are displayed on analog or digital

Figure 9-11 Outdoor air thermistor.

Figure 9-12 Variety of type J thermocouple probes.

instruments. The thermocouple produces a small voltage when two dissimilar metal wires are joined, forming a tip or junction that can be heated or cooled. The two most common thermocouple types are chromel and alumel (type K) and iron and constantan (type J). Type J sensors have been used for years and are still very popular. Type K is gaining in popularity because of its lower cost. Any manufacturer's thermocouple will work with any manufacturer's digital thermometer as long as they are both the same type. This standardization has led to the development of a wide array of different probes for many specialized applications (Figure 9-12).

Thermocouples are less accurate than wire-wound sensors but more accurate than thermistors. They may provide a temperature that is 2°F higher or lower than the actual temperature. You can test the accuracy of a thermocouple by checking the temperature of ice, which should read 32°F. Once you know the temperature error factor, you can mark it on the thermocouple. That way you can add or subtract a degree or two as needed to keep the error factor within an acceptable range for most HVACR work.

Thermocouples are relatively inexpensive and flexible. They can be attached to several locations inside of the equipment, and the equipment cover panels can then be replaced so the equipment can operate normally (Figure 9-13). With the thermocouple leads run so that they are outside the cabinet, the equipment can be operated normally. This allows technicians to diagnose what is happening to temperatures inside operating equipment.

TECH TIP

Sometimes people confuse thermometers and thermostats. The difference between a thermometer and a thermostat is that a thermometer simply indicates the temperature. A thermostat controls equipment based on the temperature it reads.

Figure 9-13 Thermocouple soldered to line in unit.

9.10 COMMON TEMPERATURE SCALES

Everyday temperatures are indicated using either the Fahrenheit or Celsius temperature scales. The Fahrenheit scale is still predominant in the United States but is seldom used anywhere else. The Celsius scale is part of the SI system of measurement and is used throughout the world. Figure 9-14 shows a comparison of the two scales.

Fahrenheit

By the early eighteenth century, many different temperature scales were proposed and used, but no clear standard had emerged. Daniel Fahrenheit produced the Fahrenheit scale in 1724. The Fahrenheit scale was based on three temperatures. The temperature of 0° was set at the lowest

Figure 9-14 Comparison of the Fahrenheit and Celsius temperature scales.

temperature he could produce in his lab using ice and salt; the freezing point of water was set at 32°; and the human body temperature was set at 96°. The boiling point of water on the Fahrenheit scale is 212° at sea level. Horse body temperature was set at 100° and was considered more stable than human body temperature.

Celsius

In 1742, Anders Celsius proposed a temperature scale with 100° as the freezing point of water and 0° as the boiling point of water. Linnaeus reversed this, placing 0° at freezing and 100° at boiling. This scale was widely adopted by scientists and was known as the Centigrade scale because of its division into 100° from freezing to boiling. The name was changed to Celsius in 1948 to honor the scientist who first conceived the scale.

TECH TIP

The Fahrenheit scale was initially set to read from the lowest temperature obtained in the lab (0°F) to horse body temperature (100°F). The Celsius scale has been set to read from the freezing point of water (0°C) to the boiling point of water (100°C). Using the Celsius scale, every degree is equal to 1/100 of the interval between freezing and boiling points. Using the Fahrenheit scale, every degree is equal to 1/180 of the interval between freezing and boiling (212°F – 32°F = 180°F). Due to the increased number of degree intervals and the lower freezing temperature, the Fahrenheit scale requires less decimals and less negative signs as compared to the Celsius scale.

9.11 ABSOLUTE TEMPERATURE

Once scientists had a way to measure temperature, they began to speculate what the coldest temperature possible would be. Most agreed that there must be a bottom, or starting point.

Charles' law was used to determine the temperature of absolute zero. In theory, if the volume of a gas keeps contracting with temperature, at some point the volume and temperature will be nothing. Scientists plotted the decrease in volume of different gases and extended the line representing the change in volume with each gas. Regardless of the gas or the starting quantity of gas, the lines all intersect at the same point, absolute zero. The coldest temperature possible where all molecular motion stops is absolute zero. This is –460°F, or –273°C.

Both the Fahrenheit and Celsius scales depend on reference points. What 5°C really means is that the temperature is 5°C warmer than the freezing point of water. A more exacting place to start measuring temperature would be at absolute zero (0°). There are two scales that do start measuring temperature from absolute zero; they are the Rankine and Kelvin scales (Figure 9-15). There are no negative temperatures in either Rankine or Kelvin because they start at absolute zero.

Figure 9-15 Fahrenheit, Celsius, Rankine, and Kelvin temperature scales: (A) boiling temperature of water; (B) standard temperature; (C) freezing temperature of water; (D) absolute zero; note that –40°C (red arrow) equals –40°F.

Both Rankine and Kelvin scales are primarily used for scientific measurements. All gas-law problems require absolute temperatures. The lack of negative temperatures makes absolute temperature scales work correctly with the ratios set up in the ideal gas law. If measurements are taken in Fahrenheit or Celsius they must be converted to Rankine or Kelvin before being used in a gas-law problem.

Rankine

The Rankine temperature scale is named after William Rankine, who proposed it in 1859. Rankine is the absolute temperature scale for Fahrenheit and has the same spacing between degrees as does the Fahrenheit scale. The numbers are just shifted so that 0° starts at absolute zero. Just as there are 180°F between freezing and boiling on the Fahrenheit scale, there is a 180°R difference between freezing and boiling on the Rankine scale as well.

Because their degree spacing is the same, conversion between Fahrenheit and Rankine is simple. Adding 460° to Fahrenheit yields Rankine; subtracting 460° from Rankine yields Fahrenheit.

Kelvin

The Kelvin temperature scale is named in honor of William Thomson, the first Baron Kelvin. Kelvin is the absolute temperature scale for Celsius and is the official temperature scale for the SI system. It has the same spacing between degrees as does the Celsius scale, just shifted so that 0° starts at absolute zero.

Because their degree spacing is the same, conversion between Celsius and Kelvin is simple. Adding 273° to Celsius yields Kelvin; subtracting 273° from Kelvin yields Celsius.

TECH TIP

Temperature scales on thermometers can go higher or lower depending on the use of the instrument. Outdoor thermometers usually have scales from -60°F to 120°F , and indoor thermometers usually range from 50°F to 90°F .

9.12 TEMPERATURE CONVERSION

As long as the United States continues to measure temperature in degrees Fahrenheit while the rest of the world uses Celsius, we will need to make conversions from one system to the other. Two primary differences in how the scales are established must be addressed. The reference point for each system is different, and the amount of temperature change represented by a degree is different.

There are 180° on the Fahrenheit scale between the freezing and boiling points of water, while the Celsius scale only has 100°C between freezing and boiling. This can be converted using a ratio. 180 divided by 100 gives us a ratio of 1.8°F for every 1°C . For people who prefer fractions, $9/5$ does the trick. This would be all we needed if 0 represented the same temperature on both scales, but it does not. Since water freezes at 32°F and 0°C , we can adjust for this by adding 32. The traditional formula for converting from Celsius to Fahrenheit is

$$(\text{Celsius} \times 1.8) + 32 = \text{Fahrenheit}$$

or if you prefer fractions

$$(\text{Celsius} \times 9/5) + 32 = \text{Fahrenheit}$$

This can be rearranged algebraically to get the formula for converting from Fahrenheit to Celsius.

$$(\text{Fahrenheit} - 32)/1.8 = \text{Celsius}$$

or if you prefer fractions

$$(\text{Fahrenheit} - 32) \times 5/9 = \text{Celsius}$$

Notice that when converting Celsius to Fahrenheit, you multiply first and then add; but when converting Fahrenheit to Celsius, you subtract first and then divide. This standard conversion process is based on comparing the freezing points of the two scales. Unfortunately, the subtle variation in execution has vexed many an aspiring technician.

9.13 CONVERSION EXAMPLES

To illustrate how this formula works, we will convert 212°F to Celsius, a temperature for which we know the answer.

The basic formula is

$$(F - 32)/1.8 = C$$

Substituting the temperature we want to convert

$$(212^{\circ}\text{F} - 32)/1.8 = C$$

That works out to

$$180^{\circ}\text{F}/1.8 = 100^{\circ}\text{C}$$

Next we will convert 100°C to Fahrenheit.

The basic formula is

$$(C \times 1.8) + 32 = F$$

Substituting the temperature we want to convert

$$(100^{\circ}\text{C} \times 1.8) + 32 = F$$

That works out to

$$180 + 32 = 212^{\circ}\text{F}$$

Now we will do a couple of examples where the answer is not as obvious. It would be useful to know what temperature Celsius is equivalent to a normal Fahrenheit temperature, so we will convert 75°F to Celsius.

The basic formula is

$$(F - 32)/1.8 = C$$

Substituting the temperature we want to convert

$$(75^{\circ}\text{F} - 32)/1.8 = C$$

That works out to

$$43^{\circ}\text{F}/1.8 = 26.9^{\circ}\text{C}$$

Next we will convert 40°C to Fahrenheit.

The basic formula is

$$(C \times 1.8) + 32 = F$$

Substituting the temperature we want to convert

$$(40^{\circ}\text{C} \times 1.8) + 32 = F$$

That works out to

$$72 + 32 = 104^{\circ}\text{F}$$

SERVICE TIP

While the two scales do not correspond at freezing, there is a temperature where the two scales align: -40° . Forty degrees below zero Fahrenheit is exactly the same temperature as 40° below zero Celsius. We can use this coincidence to build an easier system. The system has three short steps. The first and last steps are always the same regardless of which direction you are going. Only the middle step changes, and it is relatively easy to remember.

1. Add 40.
2. Multiply or divide by 1.8.
Multiply by 1.8 when converting from Celsius to Fahrenheit.
Divide by 1.8 when converting from Fahrenheit to Celsius.
3. Subtract 40.

9.14 TEMPERATURE CONVERSION TABLES

The easiest way of making the conversion is to use a conversion table, like the one on the back cover. Regardless of whether the starting temperature is Fahrenheit or Celsius, you start by finding the temperature you are converting in the center column. Look across to the number in the right column if you are converting from Fahrenheit to Celsius. If you are converting from Celsius to Fahrenheit, look at the number in the left column. To convert 75°F to Celsius, find 75 in the middle column. Looking at the right-hand column you can see that 77°F is equal to 25°C. To convert 25°C to Fahrenheit, find 25 in the center column. Looking at the left-hand column you can see that 25°C is equal to 77°F. Referring to the back cover, it is interesting to note that -40°F is equivalent to -40°C. This is the only place where the two scales coincide.

9.15 ABSOLUTE TEMPERATURE CONVERSION

The most useful conversions to absolute temperatures will be between each regular scale and its corresponding absolute scale: Fahrenheit to Rankine or Celsius to Kelvin. Fortunately these are very easy conversions to make. Fahrenheit can be converted to Rankine by adding 460; Rankine can be converted to Fahrenheit by subtracting 460. Celsius and Kelvin work in a similar manner. Adding 273 to Celsius produces Kelvin; subtracting 273 from Kelvin produces Celsius.

Since Rankine and Kelvin both start at absolute zero, they can be converted from one to the other by either multiplying or dividing by 1.8. There is no need to adjust the scales as is done with Fahrenheit and Celsius. This method produces results that are off by a little less than a degree because the temperatures for absolute zero are approximated at -460°F and -273°C.

9.16 TAKING ACCURATE TEMPERATURE READINGS

Getting accurate temperature readings requires the right equipment and the right techniques. Common temperatures read while working on HVACR equipment include air, water, and refrigerant line temperatures.

Air temperature can be read with dial-type pocket thermometers, digital pocket thermometers, or electronic temperature testers. Infrared thermometers are less desirable for air temperature readings, because they must read the temperature of objects. However, an infrared thermometer can be used to measure air by targeting the grille.

Water temperature readings can also be read with dial-type pocket thermometers, digital pocket thermometers, or electronic temperature testers. If possible, the thermometer should be inserted directly into the water stream. When using electronic thermometers, be sure that the sensor is rated for liquid immersion. Infrared thermometers do not work well for measuring liquid. An infrared thermometer can be used if the water is contacting an object that the infrared can target.

Figure 9-16 Thermocouple clamp on pipe.

Pipe temperatures are best taken with a thermocouple-type temperature tester. Probes are available with clamps that hold the thermocouple against the pipe (Figure 9-16). Bead-type thermocouples can be held against the pipe with a Velcro strap for an accurate reading (Figure 9-17). Pocket-type thermometers can be used only if the tip can be held securely against the pipe and insulated from the surrounding air. A Velcro strap or Permagum can be used to hold the tip of the thermometer against the pipe and insulate it from the surrounding air. Most infrared thermometers are not suited for measuring pipe temperature because of their distance-to-spot ratio. The emissivity of the pipe can also be a problem for shiny materials like copper. Infrared thermometers with a spot ratio of 10:1 or greater will work fine with dull pipes larger than ½ in.

Some systems are equipped with thermometer wells. These are designed for use with thermometers that have metal stems, like pocket thermometers (Figure 9-18). The

Figure 9-17 Thermocouple bead with Velcro.

Figure 9-18 Thermometer well with stem thermometer in it.

well should be filled with mineral oil to ensure good thermal contact between the well and the thermometer.

9.17 AIR TEMPERATURES

Three air temperatures are commonly read when working on air-conditioning equipment: outdoor ambient temperature, return air temperature, and supply air temperature. Ambient temperature is the temperature around the unit, typically outside. Return air is the air returning to the system from the conditioned space. Supply air is the conditioned air being supplied to the conditioned space.

Outdoor Ambient Temperature Readings

Outdoor ambient temperature readings should be taken in areas that are free from discharge air from condensing units or dryer vents and out of direct sunlight. Holding the thermometer in front of the air intake grille of the outdoor unit normally works well.

Return Air Temperature

Accurate return air temperatures can be obtained by holding a pocket or digital thermometer in front of the return air grille. Infrared thermometers can be used with return air grilles by targeting the grille.

Supply Air Temperature

Supply air temperatures can be more difficult. The unit should operate long enough for supply air temperatures to stabilize. If possible, the thermometer should be inserted inside the supply air register (Figure 9-19). When the supply air leaves the register, it mixes with room air, affecting the temperature of the supply air. Infrared ther-

Figure 9-19 Thermometer reading supply air temperature.

момeters can be used with supply air registers by targeting the supply air register. When measuring supply air temperature with an infrared thermometer, the unit must run long enough for the register to be the same temperature as the supply air.

Duct Temperatures

The temperatures read at the registers will be different than the temperature at the unit because of duct loss and gain. When checking a system performance specification, such as furnace temperature rise, it is best to check temperatures at the unit. Drilling a small hole in the ductwork allows temperature readings of the air just as it enters and leaves the unit. Holes should generally not be drilled in the actual unit or in flex duct. A hole in the wrong place in the unit can damage the unit. Flex ducts should not be pierced; poking holes in a flex duct allows air to pass between the inner and outer jacket. This increases duct loss and can lead to condensation on and inside the duct.

The return air plenum is the best location for checking return air temperatures, especially if there are several return ducts. The thermometer will read the mixed air temperature, which may be different from the temperature in individual returns.

The supply air plenum can be used on systems with a radial duct design using flex duct. The hole in the plenum should not be too close to where the plenum connects to the unit. If there are any components installed in or on the plenum, be careful to avoid them. Airflow from the return air through a bypass humidifier or bypass damper will be a very different temperature than the supply air in the plenum.

When possible, take supply air temperatures in a trunk duct leaving the plenum (Figure 9-20). This avoids the problems of radiant heat from furnace heat exchangers or return air being bypassed through a humidifier or bypass damper.

Figure 9-20 Thermometer placed in hole in supply duct.

SAFETY TIP

When drilling holes in ductwork to measure temperature, make certain you know what is on the other side of the duct; hopefully just air. Contacting a set of electric heat strips with a metal thermometer that is sticking through a metal duct can cause a direct short on a high-current device and give you a serious shock!

UNIT 9—SUMMARY

Understanding temperature measurements and conversions is essential to every aspect of HVACR work. Most HVACR jobs require temperature measurement. Temperature is the measure of the average molecular kinetic energy of a substance. The faster the molecules move, the higher the temperature. A solid emits radiant energy that is proportional to its temperature. Different types of thermometers include glass stem, dial, digital, and infrared. Thermocouples are the most common type of electronic temperature sensors. They produce a small DC voltage in response to temperature. There are four widely used tem-

perature scales: Fahrenheit, Celsius, Rankine, and Kelvin. Fahrenheit is primarily used in the United States, while Celsius is used throughout the world. Rankine and Kelvin are absolute temperature scales whose zero point is absolute zero. Getting accurate temperature readings depends upon using the correct equipment and technique.

UNIT 10

Thermodynamics—The Study of Heat

OBJECTIVES

After completing this unit, you will be able to:

1. state the first and second laws of thermodynamics.
2. compare and contrast the three basic methods of heat transfer.
3. explain the factors that affect the rate that heat transfers through various materials.
4. explain the difference between heat energy and temperature.
5. compare sensible heat to latent heat.
6. calculate heat change.
7. differentiate among saturated, superheated, and subcooled refrigerant.

10.1 INTRODUCTION

Almost everything we do in HVACR involves adding or moving thermal (heat) energy. For example, in heating we may be converting chemical energy, such as a natural gas flame, to thermal energy and distributing it through the building. In refrigeration and air conditioning we are removing heat from inside the refrigerator or house and sending it outside.

It is important to understand thermal transfer. The reason we have to heat or cool areas is because heat transfers through the walls. In the heating season it transfers out, and in the cooling season it transfers in. Put simply, HVACR technicians work with thermal energy. In this unit, we cover thermodynamics and then look at heat transfer more deeply.

10.2 FIRST LAW OF THERMODYNAMICS

Thermodynamics is the branch of science dealing with heat and the movement of energy. There are four laws of thermodynamics that describe how heat and energy behave. Two of these are of particular interest in HVACR applications. The first law of thermodynamics states that “energy can neither be created nor destroyed.” Heat cannot be “made,” but other forms of energy can be converted to heat because different forms of energy can be converted from one form to another. Energy itself is defined as the ability to do work, and heat is the transfer of energy due to temperature difference. Other common forms of energy are mechanical, electrical, and chemical, which may be converted easily from one form to another. The steam-driven turbine generator of a power plant is a device that converts heat energy into electrical energy. Chemical energy may be converted into electrical energy by the use of a battery. Electrical energy is converted into mechanical energy through the use of an electromagnetic coil to produce a push-pull motion or the use of an electric motor to create rotary motion. Electrical energy may be changed directly to heat energy by passing electrical current through wires called resistance heaters, like those used in an electric toaster, grill, or furnace. In all of these transformations, energy is neither created or destroyed; it is just changed from one form of energy to another.

10.3 SECOND LAW OF THERMODYNAMICS

The second law of thermodynamics states that “to cause heat energy to travel, a temperature difference must be established and maintained.” Heat energy travels downward on the intensity scale. Heat from a higher temperature (intensity) material will travel to a lower temperature (intensity) material, and this process will continue as long as the temperature difference exists. The rate of travel varies directly with the temperature difference. The higher the temperature difference, commonly called the delta temperature, or ΔT , the greater the rate of heat travel. The lower the ΔT , the lower the rate of heat travel.

10.4 METHODS OF HEAT TRANSFER

There are three principal ways that heat is transferred:

1. Conduction
2. Convection
3. Radiation

Most refrigeration systems utilize all three methods. These three methods of heat transfer are shown in Figure 10-1.

TECH TIP

Heat is always on the move. It is moving constantly from a warmer body to a cooler body. This movement can be slowed with insulation, but no matter how thick the insulation is, heat will continue to move through it until both bodies have reached equilibrium and are at the same temperature. For this reason it is very difficult to store heat for long periods of time without significant loss in the quantity of heat being stored.

10.5 CONDUCTION

Conduction is described as the transfer of heat between the closely packed molecules of a substance, or between substances that are in good contact with one another. When

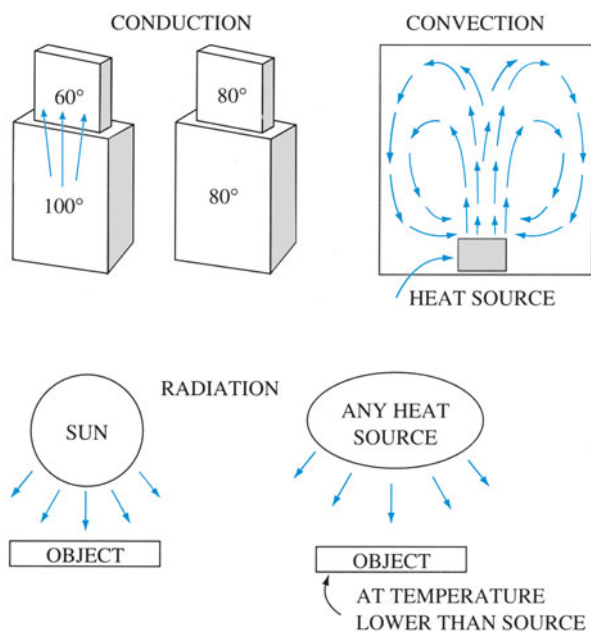

Figure 10-1 Three methods for transferring heat.

heat transfers by conduction in a single substance, such as a metal rod, movement of heat continues until there is a temperature balance throughout the length of the rod. With one end of the rod in a flame and the other end in the air, heat will travel from the end in the flame to the end in the air. Heat will continue to travel through the rod as long as one end is hotter than the other. Even after the rod is removed from the flame, heat will continue to travel from the hotter end to the cooler end until both ends are the same temperature.

If the rod is immersed in water, the rapidly moving molecules on the surface of the rod will transmit some heat to the molecules of water, and still another transfer of heat by conduction takes place. As the outer surface of the rod cools off, there is still some heat within the rod, and this will continue to transfer to the outer surfaces of the rod and then to the water, until a temperature balance is reached.

The rate of heat transfer will vary according to the ability of the material to conduct heat. Solids, on the whole, are much better conductors than liquids; in turn, liquids conduct heat better than gases or vapors.

Most metals, such as silver, copper, steel, and iron, conduct heat fairly rapidly. Many other solids, such as glass, wood, or other building materials, transfer heat at a much slower rate and therefore are used as insulators.

TECH TIP

Materials that are excellent electrical conductors also tend to be excellent thermal conductors. Similarly, materials that are good electrical insulators also tend to be good thermal insulators. Of course there are exceptions. Materials such as ceramics can be designed to be either an insulator or a conductor of electricity or heat. One particular type of ceramic is actually considered to be a superconductor, meaning it has extremely low electrical and heat resistance.

Material	Conductivity <i>k</i>

Figure 10-2 Conductivities for common building and insulating materials; *k* values expressed in BTU/hr/ft²/°F/in thickness of material.

Copper is an excellent conductor of heat, as is aluminum. These substances are ordinarily used in the construction of heat-transfer coils like evaporators and condensers. Steel and iron are also used for some types of heat-transfer devices.

The rate at which heat may be conducted through any material is dependent on factors like the thickness of the material, its cross-sectional area, the temperature difference between the two sides of the material, the heat conductivity (*k* factor) of the material, and the time duration of the heat flow. The table in Figure 10-2 gives the heat conductivities (*k* factors) of some common materials.

Note that the *k* factors are given in BTU/hr/ft²/°F/in of thickness of the material. The formula for heat transfer using these factors is

$$\text{Heat in BTUH} = \frac{A \times \Delta T \times k}{X} \quad (10.1)$$

where

A = cross-sectional area, ft²

k = heat conductivity, BTU/hr/ft²/°F/in

ΔT = temperature difference between the two sides, °F

X = thickness of material, in

Metals with a high conductivity are used within the refrigeration system itself because it is desirable that rapid heat transfer occur in both evaporator and condenser. The evaporator is where heat is removed from whatever is being cooled; the condenser dissipates this heat to another medium or space.

In the case of the evaporator, the product or air is at a higher temperature than the refrigerant within the tubing, and there is a transfer of heat from the warm air into the cool refrigerant in the evaporator. In the condenser, however, the refrigerant vapor is at a higher temperature than the cooling medium traveling through the condenser, and heat transfers out of the warm refrigerant in the condenser into the cooler surrounding air.

Plain tubing, whether copper, aluminum, or another metal, will transfer heat according to its conductivity, or *k* factor, but this heat transfer can be increased through the addition of fins on the tubing. They will increase the

area of heat-transfer surface, thereby increasing the overall efficiency of the system. If the addition of fins doubles the surface area, it can be shown by the use of Equation 10-1 that the overall heat transfer will be doubled compared to that of plain tubing.

10.6 CONVECTION

Another means of heat transfer is by motion of the heated material itself. Convection is limited to heat transfer within a liquid or a gas. When a material is heated, convection currents are set up within it, and the warmer portions of it rise, since heat brings about the decrease of a fluid's density and an increase in its specific volume.

SERVICE TIP

Homeowners and building operators sometimes like to put up their own thermometers in a room. That thermometer reading sometimes is the one you will hear them talking about when they complain about room temperature. There are several factors that will affect the thermometer reading that may result in it being different from the room thermostat. First, the room thermostat is usually close to a height of five feet and should be located on an inside wall. If their thermometer is higher or lower than that, it will read a different temperature. Second, if their thermometer is near an outside wall, it will read higher or lower depending on the season of the year. Certainly a thermometer that is in a window can have wide swings in temperature. One common thermometer people use gives indoor and outdoor temperature readings. By its design, it must be located on an outside wall so that its probe can go to the outside of the building. Those temperature readings will be significantly different most of the time from the room thermostat.

Natural Convection

Natural convection occurs when fluid circulates because of the density changes that are the result of the fluid heating up and cooling down. Systems that rely entirely on natural convection are called passive systems. Air within a refrigerator is a prime example of the results of convection currents (Figure 10-3). The air in contact with the cooling coil of a refrigerator becomes cool and therefore denser and begins to fall to the bottom of the refrigerator. In doing so, it absorbs heat from the food and the walls of the refrigerator, which, through conduction, has picked up heat from the room. After heat has been absorbed by the air it expands, becoming lighter, and rises until it again reaches the cooling coil where heat is removed from it. The convection cycle repeats as long as there is a temperature difference between the air and the coil. In commercial units, baffles may be constructed within the box to direct the air in the desired airflow patterns.

Water heated in a pan will be affected by the convection currents set up within it through the application of heat. The water nearest the heat source absorbs heat, becomes warmer, and expands. As it becomes less dense, it rises and is replaced by the other water, which is cooler and denser.

Figure 10-3 Convection currents caused by temperature differential.

Forced Convection

Forced convection is the process of moving a fluid using mechanical means to increase heat transfer. Fans are used to move gases; pumps are used to move liquids. Systems that use fans or pumps to increase convection are called active systems.

Natural convection currents in air or water distribute the temperature only to a certain extent. Natural convection currents will not keep a room's temperature consistent from floor to ceiling. A temperature difference of 10°F from floor to ceiling in a room with a wood stove is common. When there is a large temperature difference from the floor to the ceiling, additional air circulation is needed to break up the stratified air temperature. Ceiling fans like the one shown in Figure 10-4 can help distribute the heated air more evenly.

Figure 10-4 Ceiling fans in vaulted ceilings can help redistribute warm air that has collected at the top of the ceiling.

Figure 10-5 Correlation between the absolute temperature of an object and its color.

10.7 RADIATION

A third means of heat transfer is through radiation. Radiant heat energy travels by waves similar to light or sound waves. These waves travel in a straight path and require no medium between the heat source and the heated object. The sun's rays heat the earth by means of radiant heat waves, which travel through space to heat the earth. Four factors control the amount of energy transmitted between a radiation source and an object: the frequency of the radiation, the absolute temperature of the source, the surface area of the source, and the distance between the source and the object.

Radiant energy waves exist at many different frequencies. The frequency is related to the distance between the peaks of the waves. The shorter the distance, the higher the frequency. Higher frequency radiation is more powerful than lower frequency radiation.

The total amount of radiant energy emitted by an object increases dramatically as its absolute temperature increases. Doubling the absolute temperature increases the emitted energy by a factor of 16. The amount of radiant energy emitted by a radiation source is also directly related to its surface area. Twice as much surface area produces twice as much radiant energy.

Heat transfer through radiation does not result in an even distribution of heat. The amount of radiant energy transferred decreases with the square of the distance. This means that doubling the distance decreases the amount of energy transmitted to a fourth of the original amount. A fireplace heats through radiation. The further you get away from the fireplace, the colder it is. Next to the fireplace is very warm, but a few feet away can feel much cooler.

Radiant energy travels in straight lines and heats objects, not air. While facing the fireplace in a cold room, your front is warm but your back is cold because it is turned away from the fire. If someone steps between you and the fireplace, your source of heat is cut off and you feel instantly cold.

All objects absorb radiant energy to some extent. When radiant energy strikes matter, it can be absorbed, reflected, or transmitted. The amount of energy absorbed versus the amount of energy reflected and transmitted depends on the characteristics of the material. Solids absorb more radiant energy than liquids; liquids absorb more than gases. Dark-colored solids absorb more energy than they reflect, while light-colored solids reflect more than they absorb. The name for an object that is a perfect absorber of radiation is a black body.

All objects whose temperature is above absolute zero also emit radiation. The amount of radiant energy emitted equals the amount of energy absorbed by the object. Black bodies are also perfect radiation emitters. Radiant objects emit many

frequencies of radiation, but they tend to emit more radiation of one particular frequency. This primary frequency changes with the absolute temperature of the object. When the primary frequency is within the visible light spectrum, the object appears that color. Figure 10-5 shows the correlation between the absolute temperature of an object and its color.

TECH TIP

Since radiant energy has little effect on gases, radiant heaters tend to heat the objects in a room without heating the air in the room. This has the advantage of heating people quickly. It also can mean that people can be comfortable at lower room temperatures. The air temperature does rise because the air is heated by the objects in the room, but the primary purpose of radiant heat is not to heat the air but the objects.

10.8 HEAT-TRANSFER PROCESSES

Heat is the transfer of energy because of a difference in temperature. The reaction of matter to the addition or deletion of heat is described as either a sensible or a latent process. A sensible process results in a temperature change, while a latent process results in a physical state change. Notice that these terms describe how heat affects substances; they are not names for different types of heat.

10.9 SENSIBLE HEAT

Heat that can be felt or measured is called sensible heat because it can be sensed. A sensible heat process causes a change in the temperature of a substance but not a change in state. For example, hot air travels across a cold evaporator coil and is reduced in temperature. This is called a sensible heat process because the air temperature was changed when heat was removed from it. Anytime a heat transfer results in a temperature change, that process can be called a sensible heat process.

10.10 SPECIFIC HEAT CAPACITY

Specific heat capacity is a factor that allows technicians to calculate the exact amount of heat required to produce a specific temperature rise in a substance. Calculating how much heat it takes to change the temperature of water is

Water	1.00
Ice	0.50
Air (dry)	0.24
Steam	0.48
Aluminum	0.22
Brass	0.09
Lead	0.03
Iron	0.10
Mercury	0.03
Copper	0.09
Alcohol	0.60
Kerosene	0.50
Olive oil	0.47
Glass	0.20
Pine	0.67
Marble	0.21

Figure 10-6 Specific heats of common substances (BTU/lb/°F).

relatively easy. In either the traditional or SI measurement systems, the weight of the water is multiplied by the difference in temperature. This is because the units of heat are defined by a temperature change in water.

However, everything does not take the same amount of heat to change temperature. For example, it takes far less heat to change the temperature of metal than glass. Each substance has its own specific heat. The specific heat is also different for different states of the same substance. For example, the specific heat of water is 1.0 BTU/lb, while the specific heats of both ice and steam are approximately 0.5 BTU/lb. Figure 10-6 shows the specific heat capacity of several common substances. It is important to use the correct specific heat value when calculating heat change in a substance.

In traditional units, the specific heat capacity is the number of BTUs required to change the temperature of 1 lb of a substance 1°F. Water has a specific heat capacity of 1, since the definition of the BTU is based on a 1°F temperature change in water. A substance that requires only half as much heat as water would have a specific heat capacity of 0.5 BTU/lb, while something that takes twice as much heat would have a specific heat capacity of 2.0 BTU/lb. Things that are easily heated have low specific heat capacities, while things that are slow to heat have high specific heat capacities.

The formula for changing the temperature of anything is

$$\text{heat quantity} = \text{weight} \times \text{temperature difference} \times \text{specific heat}$$

In traditional units, the weight is measured in pounds and the temperature in degrees Fahrenheit. The formula becomes

$$\text{BTU} = \text{lb} \times ^\circ\text{F} \Delta T \times \text{specific heat capacity in BTU/lb/}^\circ\text{F}$$

In the SI system, specific heat capacity is commonly given as the number of kilojoules (kJ) required to change 1 kg of a substance 1°K. The formula becomes

$$\text{kJ} = \text{kg} \times ^\circ\text{K} \Delta T \times \text{specific heat capacity in kJ/kg/}^\circ\text{K}$$

10.11 LATENT HEAT

The word *latent* means hidden. Latent heat is hidden heat because there is no accompanying temperature change to sense. Of course the heat exists—it goes into the molecules to change their state. Latent heat refers to a heat transfer that causes a change in state but not a change in temperature. For example, the refrigerant in the evaporator coil of an air conditioner boils from a liquid to a gas while it is absorbing heat from the warm air passing over the coil. Since the refrigerant is changing state and not temperature, this heat-transfer process is called a latent heat process because the result of the heat transfer is a change in state, not a change in temperature. Latent heat is always involved in a change of state. There are several possible state changes, each with its own latent heat value. Each of these changes has a name that identifies the state change. Figure 10-7 lists the different types of state changes.

It takes a lot more energy to change the state of a substance than it does to change its temperature. It takes 144 BTU to change 1 lb of ice to water, but it only takes 0.5 BTU to change the temperature 1°F. The state changes involving gas require even more heat. It takes 970 BTU to boil a pound of water, but it only takes 180 BTU to raise the temperature of 1 lb of water from 32°F to 212°F. The formula for calculating a state change is

$$\text{BTU} = \text{weight} \times \text{latent heat factor}$$

The latent heat factor is different for different substances. It is also different for different state changes of the same substance. Figure 10-8 lists the latent heat factors for a few common substances.

10.12 APPLICATION OF HEAT-TRANSFER PROCESSES

Simply stated, a sensible heat process causes a change in temperature; a latent heat process causes a change in state. A substance can either change temperature or change state, but it cannot change both at the same time. Water will not boil until it reaches 212°F, but once it does, its temperature will not change. A heat-transfer process requires a heat source to supply the heat and a heat sink to absorb the heat. One can undergo a sensible change while the other undergoes a latent change. In the evaporator coil shown in Figure 10-9, the refrigerant is boiling from a liquid to a gas and absorbing heat. This is a latent change. The fact that the refrigerant is changing state keeps it cold even as it is absorbing heat. The air blowing over the evaporator is changing temperature from warm to cool. This is a sensible change. The sensible change in air temperature is the goal.

Figure 10-9 The refrigerant in this coil is undergoing a latent change from liquid to vapor while the air is undergoing a sensible change from warm to cool.

10.13 CALCULATING HEAT CHANGE

The specific heat formula is used to calculate the amount of heat required to change the temperature of a substance; the latent heat formula is used to calculate the amount of heat required to change the state of a substance. Both formulas must be used if the change will involve both a temperature change and a state change. Something cannot change state and temperature at the same time, but it can change temperature and then change state. The process of changing water from below-freezing ice to superheated steam is illustrated in Figure 10-10.

The line from A to B in Figure 10-10 shows the temperature change in the ice from 10°F to 32°F. The line from B to C shows the 32°F ice melting to 32°F water. Notice that the temperature of the water is the same as the ice. The line from C to D shows the water temperature rising from 32°F to 212°F. The line from D to E shows the 212°F water boiling to 212°F steam. Notice that the steam temperature is the same as the water temperature. Finally, the line from E to F represents raising the steam temperature from 212°F to 230°F. Each of these steps is solved independently, and the results are summed to solve for the overall amount of heat required.

- The heat required to increase the temperature of 1 lb of ice from 10°F to 32°F is calculated using the specific heat formula:

$$\text{BTU} = \text{lb} \times \text{°F} \Delta T \times \text{specific heat capacity in BTU/lb/°F}$$

$$\text{BTU} = 1 \text{ lb} \times 22 \times 0.5 = 11 \text{ BTU}$$

- The heat required to melt 1 lb of ice is calculated using the latent heat formula:

$$\text{BTU} = \text{lb} \times \text{latent heat factor in BTU/lb}$$

$$\text{BTU} = 1 \times 144 = 144 \text{ BTU}$$

- The heat required to increase the temperature of 1 lb of water from 32°F to 212°F is calculated using the specific heat formula:

$$\text{BTU} = \text{lb} \times \text{°F} \Delta T \times \text{specific heat capacity in BTU/lb/°F}$$

$$\text{BTU} = 1 \text{ lb} \times 180 \times 1 = 180 \text{ BTU}$$

- The heat required to boil 1 lb of water is calculated using the latent heat formula:

$$\text{BTU} = \text{lb} \times \text{latent heat factor}$$

$$\text{BTU} = 1 \times 970 = 970 \text{ BTU}$$

Figure 10-10 Chart demonstrating sensible and latent heat relationships in melting ice, changing ice to water and water to steam.

- The heat required to increase the temperature of a pound of steam from 212°F to 230°F is calculated using the specific heat formula:

$$\text{BTU} = \text{lb} \times ^\circ\text{F} \Delta T \times \text{specific heat capacity in BTU/lb}$$

$$\text{BTU} = 1 \text{ lb} \times 18 \times 0.5 = 9 \text{ BTU}$$

It is evident that changes of state require much more heat than changes in temperature. The total amount of heat required for the temperature change from 10°F to 230°F is 210 BTU, while the total amount of heat required to change state from ice to water and from water to steam is 1,114 BTU. The latent heat is the turbocharger of the refrigeration cycle. Much greater amounts of heat can be moved by changing the refrigerant's state than by changing its temperature.

10.14 EXAMPLE HEAT CALCULATION

Calculate the amount of heat needed to change 10 lb of ice at -20°F to steam at 250°F.

- The heat required to increase the temperature of 10 lb of ice from -20°F to 32°F is calculated using the specific heat formula:

$$\text{BTU} = \text{lb} \times ^\circ\text{F} \Delta T \times \text{specific heat capacity in BTU/lb/}^\circ\text{F}$$

$$\text{BTU} = 10 \text{ lb} \times 52 \times 0.5 = 260 \text{ BTU}$$

- The heat required to melt 10 lb of ice is calculated using the latent heat formula:

$$\text{BTU} = \text{lb} \times \text{latent heat factor}$$

$$\text{BTU} = 10 \times 144 = 1,440 \text{ BTU}$$

- The heat required to increase the temperature of 10 lb of water from 32°F to 212°F is calculated using the specific heat formula:

$$\text{BTU} = \text{lb} \times ^\circ\text{F} \Delta T \times \text{specific heat capacity in BTU/lb/}^\circ\text{F}$$

$$\text{BTU} = 10 \text{ lb} \times 180 \times 1 = 1,800 \text{ BTU}$$

- The heat required to boil 10 lb of water is calculated using the latent heat formula:

$$\text{BTU} = \text{lb} \times \text{latent heat factor}$$

$$\text{BTU} = 10 \times 970 = 9,700 \text{ BTU}$$

- The heat required to increase the temperature of a pound of steam from 212°F to 250°F is calculated using the specific heat formula:

$$\text{BTU} = \text{lb} \times ^\circ\text{F} \Delta T \times \text{specific heat capacity in BTU/lb/}^\circ\text{F}$$

$$\text{BTU} = 10 \text{ lb} \times 38 \times 0.5 = 190 \text{ BTU}$$

- Finally, sum the results

$$260 \text{ BTU} + 1,440 \text{ BTU} + 1,800 \text{ BTU} + 9,700 \text{ BTU} + 190 \text{ BTU} = 13,390 \text{ BTU}$$

10.15 SATURATED LIQUID-GAS MIXTURES

The word *saturated* means completely full. When a sponge is saturated with water, it is holding all the water it can possibly hold. If you try to add more water, some water will spill out because there is nowhere for it to go. When a liquid is saturated with heat, it has all the heat it can hold and still remain a liquid. When you add additional heat to a saturated liquid, some of the liquid changes to a gas. The gas that boils off of a saturated liquid is called a saturated gas. If heat

Figure 10-11 Even though these cylinders have different amounts of liquid refrigerant in them, they are the same pressure because they are the same temperature.

is removed from a saturated gas, some of the gas will condense to a liquid. The saturation point is the boiling point. As long as the liquid-gas mix remains at a constant pressure and some liquid remains, the temperature will remain the same. Additional heat does not change the temperature; it simply makes more saturated gas. This concept of saturation helps explain why a liquid's temperature remains stable when it boils. After you reach the boiling point, any extra heat goes into turning some of the liquid to gas rather than raising the temperature of the liquid.

While it is technically possible to have a saturated gas and not have any saturated liquid along with it, in practice, where there is saturated gas there is also saturated liquid. For this reason, many texts refer to saturated mixtures when discussing either saturated gases or saturated liquids.

Saturated gases do not follow the ideal gas laws. The liquid in a saturated mixture will continue to vaporize until the gas pressure reaches the saturation point for the temperature of the mixture. The pressure of a cylinder of saturated refrigerant with 5 lb of refrigerant will have the same pressure as a cylinder with 20 lb of refrigerant if they are both at the same temperature. For saturated mixtures, the pressure is determined entirely by the temperature and not by the quantity of refrigerant (Figure 10-11).

SERVICE TIP

A drop in cylinder pressure is a common problem encountered when charging refrigerant vapor from a cylinder into a system. This does not happen because there is less refrigerant in the cylinder, but because the remaining liquid in the cylinder cools off as the vapor leaves. When vapor boils off of the liquid, it removes heat from the liquid, dropping its temperature. When the temperature of a saturated mixture drops, so does the pressure. Heating the cylinder with warm water can offset this. When the liquid temperature is raised, the pressure comes up as well.

10.16 USING PRESSURE-TEMPERATURE CHARTS

Remember that the boiling point, or saturation temperature, is controlled by pressure. The higher the pressure is, the higher the saturation temperature will be. The pressure and temperature of any saturated mixture go up and down together. If you know one, you can find the other. Charts called pressure-temperature charts, or PT charts for short, are commonly used in refrigeration (Figure 10-12). These charts correlate the saturation temperature and pressure for commonly used refrigerants. Most of these charts list temperature in a column on the left-hand side of the chart and corresponding pressures in columns on the right-hand side of the chart. To use the chart, find the saturation temperature in the left column and follow across that same row to the column under the refrigerant being used. That lists the pressure of the refrigerant that corresponds to that particular saturation temperature. In Figure 10-12, for example, 40°F in the left-hand column corresponds to 68.5 psig in the column under R-22.

Of course the chart can be used the other way also. Find the pressure in the column under the refrigerant and then follow across that same row to the temperature column on the outside. This lists the saturation temperature for the refrigerant at that particular pressure. Again in Figure 10-12, for example, 124.1 psig under the R-134a column corresponds to 100°F in the temperature column on the left-hand side.

10.17 SUPERHEATED GAS

Remember that when heat is added to a saturated mix, the temperature does not change. More liquid turns to gas, but the temperature remains the same. However, what happens if enough heat is added to a saturated mixture until all the liquid has turned to gas? Now, if more heat is added, the gas temperature will rise because there is no more liquid to boil. When a gas is heated above its boiling point, it is

called a superheated gas. In theory it is possible to have a gas that has no liquid in it and is still at the saturation point. However, in practice, if there is only gas present, it is usually superheated. What happens when heat is removed from a superheated gas? The temperature of a superheated gas drops as it is cooled until it reaches the saturation point. If heat continues to be removed after the gas reaches the saturation point, some of the gas will turn back to liquid. When the saturated gas begins to change to liquid, the temperature remains the same.

10.18 SUBCOOLED LIQUID

As long as there is some gas in a saturated mix, the removal of heat will result in some of the gas changing to liquid at the same temperature. After all the gas has turned to liquid, if more heat is removed, the liquid temperature will drop because there is no more gas to turn into liquid. When a liquid is cooled below its boiling point it is called a subcooled liquid.

10.19 DISTINGUISHING AMONG SATURATED, SUPERHEATED, AND SUBCOOLED

Refrigerant can be found in a refrigeration system as a superheated gas, a saturated mixture, or a subcooled liquid. Determining the condition of the refrigerant is an important

step in working on refrigeration systems. It is not really difficult to determine if the refrigerant in a part of a refrigeration system is saturated, superheated, or subcooled. All that is needed are the following:

- An accurate temperature reading
- An accurate pressure reading
- A pressure-temperature chart for the type of refrigerant involved

Take accurate pressure and temperature readings where the state of the refrigerant is to be identified. Use a saturated pressure-temperature chart to look up the saturation temperature that corresponds to the pressure reading.

Saturated Mix

If the actual temperature reading is within 3° of the temperature on the chart, the refrigerant is most likely saturated. Ideally it should be dead on, but a slight measurement error on either the pressure or temperature reading can make it difficult to get a perfect reading.

Superheated Vapor

If the actual temperature reading is more than 3° above the temperature on the chart, the gas is superheated.

Figure 10-13 Comparison of a saturated mixture of liquid and vapor, a superheated vapor, and a subcooled liquid.

Subcooled Liquid

If the actual temperature reading is more than 3° degrees below the saturated temperature on the chart, the liquid is subcooled.

This procedure is summarized below.

1. Measure the refrigerant pressure and temperature.
2. Look up the saturation temperature for the refrigerant pressure on a PT chart.
3. Compare the chart temperature to the actual temperature.

Figure 10-13 illustrates the difference among a saturated mix, a superheated vapor, and a subcooled liquid.

UNIT 10—SUMMARY

Thermodynamics is the study of heat. The first law of thermodynamics states that energy cannot be created or destroyed; the second law of thermodynamics states that heat travels from hot to cold. Heat can travel through conduction, convection, or radiation. Conduction is the transfer of heat through a material by physical contact, convection is heat transfer by fluid circulation, and radiation is heat transfer by waves of radiant energy.

A sensible heat-transfer process results in a temperature change; a latent process results in a change of state. It takes more heat to change the state of matter than to change its temperature. Heat changes that involve both temperature changes and state changes must be broken down into steps before solving.

A saturated mixture is a mixture of liquid and vapor at the boiling point. The pressure or temperature of a saturated mixture can be predicted using a pressure-temperature chart. A gas whose temperature is above the saturation temperature contains no liquid and is called a superheated gas. A liquid whose temperature is below the saturation temperature contains no gas and is called a subcooled liquid.

UNIT 10—REVIEW QUESTIONS

1. Summarize the first and second laws of thermodynamics.
2. How does temperature difference affect the rate that heat travels?
3. List the three methods of heat transfer, and give an example of each.
4. What is the relationship between electrical conductivity and thermal conductivity?
5. List two materials that are considered to be good thermal conductors.
6. According to their k values, which material is a better insulator: expanded polystyrene or expanded polyurethane?
7. Explain why the addition of fins on the tubing will increase the rate of heat transfer.
8. Describe the process of natural convection.
9. What factors determine the amount of radiant energy that is transferred between two objects?
10. Explain the relationship between radiant energy and color.
11. Can a substance change temperature and state at the same time? Explain.
12. Describe the following terms: *fusion*, *liquefaction*, *vaporization*, *condensation*, *deposition*, and *sublimation*.
13. Define *sensible heat*.
14. Define *latent heat of fusion*.
15. What is a saturation pressure-temperature chart?
16. The refrigerant R-22 in a system component has a pressure of 70 psig and a temperature of 50°F. Is it saturated, superheated, or subcooled?
17. The refrigerant R-134a in a system component has a pressure of 35 psig and a temperature of 40°F. Is it saturated, superheated, or subcooled?
18. The refrigerant R-410a in a system component has a pressure of 340 psig and a temperature of 95°F. Is it saturated, superheated, or subcooled?
19. Calculate the amount of heat in BTUs required to change the temperature of 6 lb of copper from 75°F to 100°F.
20. Calculate the amount of heat in BTUs required to turn 5 lb of 10°F ice to 242°F steam.

Pressure and Vacuum

OBJECTIVES

After completing this unit, you will be able to:

1. explain the relationships between atmospheric pressure, gauge pressure, and absolute pressure.
2. convert atmospheric, absolute, gauge, and vacuum pressures to different scales.
3. define *head pressure* and tell how it is used.
4. explain how a manometer measures pressure.
5. explain how a refrigeration gauge measures pressure.
6. describe how gas responds to changes in temperature, volume, and pressure.
7. solve for new pressure, temperature, or volume using the ideal gas law.

11.1 INTRODUCTION

Pressure is a fundamental physical property that is measured when servicing HVACR equipment. Hydronic, pneumatic, refrigeration, and air systems all depend upon pressure differences to create flow, and HVACR technicians must be familiar with pressure and vacuum readings so they can properly install, service, and repair these systems. The operation of HVACR equipment depends on controlling system pressures. This unit covers the different types of pressure readings and how to convert one type of reading into another.

11.2 PRESSURE

Pressure is a comparative measurement. It compares force pushing on a surface to the area supporting the force. Pressure is uniformly distributed over the surface it is pushing on. The pressure on any surface can be determined by dividing the force applied by the area it is pushing against.

Different states of matter exert pressure in different ways. A solid exerts pressure downward because of gravity. Liquids exert pressure downward and outward because of gravity. Gases exert pressure in all directions against the walls of their container (Figure 11-1).

The force is normally expressed as weight. The pressure created by an object that weighs 100 lb and has a base

of 100 in² is 100 lb/100 in² = 1 pound per square inch. We abbreviate this as 100 psi. If the object weighed 100 lb but had a base area of only 50 in², the pressure would be 100 lb/50 in² = 2 psi, because the same weight is supported by a smaller area. If the same 100 lb was supported by a larger base of 200 in², the pressure would be 100 lb/200 in² = 0.5 psi. All that is necessary to calculate pressure is to divide the force by the area. In standard units, pressure is measured in pounds per square inch (psi).

11.3 LIQUID COLUMN PRESSURE

Another common way to measure pressure is to measure how high a column of liquid the pressure will support. In the case of atmospheric pressure, the atmosphere will support a column of mercury about 30 inches high. What this means is that a column of mercury 30 inches high weighs the same as the column of air pushing on it.

Higher pressures are measured in inches of mercury because mercury is heavy. Lower pressures are measured in inches of water column, because water is much lighter. While atmospheric pressure will support a column of mercury 30 inches high, it will support a column of water 34 feet high! In air conditioning, we use mercury columns to measure vacuum. A vacuum is a pressure less than atmospheric pressure. Since standard atmospheric pressure measures 29.92 inches of mercury, inches of mercury can be used to measure vacuum by comparing the vacuum to atmospheric pressure. A 10-inch mercury vacuum will only support a mercury column 19.92 inches high, 10 inches less than the atmospheric pressure of 29.92 inches mercury. Water columns are used to measure the air pressure in ductwork and the gas pressure in gas furnaces because the pressures in an air duct and in a gas line are much smaller pressures.

11.4 ATMOSPHERIC PRESSURE

The air around us exerts a pressure because it has weight. The weight of all the air sitting on top of each square inch of surface area is about 15 lb at sea level. This varies

Figure 11-1 A solid exerts pressure down, a liquid exerts pressure down and to the sides, and a gas exerts pressure in all directions.

depending upon the elevation of your location. The higher the elevation, the lower the atmospheric pressure. Since higher elevations have less air above them, the column of air weighs less, making the air pressure lower. Standard atmospheric pressure at sea level with a temperature of 59°F is 14.7 psi, or 101.325 kilopascals (kPa) for SI. In mercury column measurement, that is 29.92 inches of mercury (in Hg) or 760 millimeters of mercury (mm Hg).

The atmospheric pressure at any location on earth will also change with the weather. Both temperature and humidity changes affect the atmospheric pressure. Higher temperature and higher relative humidity both produce lower atmospheric pressure. Higher temperature causes the air to expand, reducing its density and weight, which reduces the atmospheric pressure. Water molecules are lighter than either nitrogen or oxygen molecules. Air with a high relative humidity has more water molecules and fewer nitrogen and oxygen molecules than dry air, making high relative-humidity air lighter than dry air.

11.5 BAROMETRIC PRESSURE

Barometric pressure is a term that is used for the current atmospheric pressure. Meteorologists study barometric pressure to predict weather patterns. A barometer is a device designed to measure the atmospheric pressure. Atmospheric pressure was first demonstrated by the type of simple barometer shown in Figure 11-2.

Early experimenters used a glass tube about 36 in long and closed at one end, an open bowl, and a supply of mercury. They filled the tube with mercury and inverted it in the bowl of mercury, holding a finger at the open end to keep the mercury from spilling out while the tube was inverted. Upon removal of the finger, the level of the mercury in the tube dropped somewhat, leaving a vacuum at the closed top of the tube. The atmospheric pressure bearing down

Figure 11-2 Column of mercury supported by normal atmospheric pressure.

on the open bowl of mercury forced the mercury in the tube to stand up to a height determined by the air pressure. Standard air pressure at sea level and 59°F is 29.92 in Hg. That is 760 mm in SI. That is how barometric pressure came to be measured in inches of mercury (in Hg).

SAFETY TIP

Mercury is considered to be a hazardous chemical, and it must be disposed of properly when an instrument containing mercury is to be disposed of. Mercury can contaminate an area, resulting in an expensive cleanup operation if it is carelessly discarded on the floor of an office, school, hospital, or any other public area. Mercury vapors have been associated with a number of health issues. Therefore, anytime mercury is spilled, you must notify the proper authorities so that its potential threat can be determined and an appropriate method of removing the contamination can be done. Be very careful when instruments are used that contain mercury to avoid any accidental spillage.

Although early scientists did touch mercury with their hands, this is not safe, because mercury is toxic. Handling of mercury should be avoided.

One problem with this type of instrument is that it is not very portable. The aneroid barometer was developed as a more portable instrument. Its operating mechanism is an evacuated bellows called an aneroid cell (Figure 11-3). All the air is removed from the bellows, but it has a spring inside that balances standard atmospheric pressure and prevents the bellows from collapsing. An increase in the atmospheric

Figure 11-3 Aneroid cell barometer.

pressure causes the bellows to contract; a decrease in pressure causes it to expand. The movement of the bellows moves a needle that indicates the atmospheric pressure.

11.6 LIQUID COLUMN PRESSURE MEASUREMENT

A manometer is one type of device used in the refrigeration and air-conditioning field for the measurement of pressure. This type of pressure gauge uses a liquid, usually mercury, water, or gauge oil, as an indicator of the amount of pressure involved. The water column manometer is customarily used when measuring pressures like gas pressures or pressures in air ducts because the low density of water makes it suitable for measuring small amounts of pressure.

SERVICE TIP

There are electronic devices that can measure air pressure so accurately that they can tell the difference in altitude of a distance as little as 5 ft. These devices use small electronic sensors to determine the difference in pressure. Most of these instruments use a piezo crystal as their sensor. A piezo crystal is a crystal that changes its electrical resistivity as a result of external force. As the cost of piezo crystal sensors decreases, their use in air conditioning will increase.

A simple open-arm manometer is shown in Figure 11-4. The U-shaped glass tube is partially filled with water and is open at both ends. The water is at the same level in both arms of the manometer, because both arms are open to the atmosphere, and no external pressure is being exerted on them.

Figure 11-4 U-tube manometer.

Figure 11-5 When pressure is applied to one side of the manometer, the liquid in that side is forced down and the other side is forced up.

Figure 11-5 shows the manometer in use with one arm connected to a source of positive pressure that is being measured. The amount of pressure being applied is shown by the difference in fluid level from one side to the other. In this case, the pressure is 2 in. water column.

A space that is void, or lacking any pressure, is described as having a perfect vacuum. If the space has pressure less than atmospheric pressure, it is defined as being a partial vacuum. It is customary to express this partial vacuum in inches of mercury vacuum, abbreviated as in Hg vacuum.

If a vacuum pump pulls a partial vacuum on the left arm of the manometer, as shown in Figure 11-6, atmospheric pressure will push the mercury in the right arm lower and the mercury on the left higher. The measured vacuum is the difference between the two sides of the manometer, in this case 2 in. Hg vacuum.

Liquid column measurement in SI uses millimeters of mercury. Atmospheric pressure is equal to 760 mm Hg.

11.7 GAUGE PRESSURE

The gauges used in the HVACR field typically measure pressure compared to atmospheric pressure. Atmospheric pressure is used as the starting point, so the gauges are calibrated to read 0 at atmospheric pressure. Pressures above atmospheric pressure register as a positive pressure, while pressures below atmospheric pressure register as a vacuum. A "g" is added to the end of psi to indicate gauge pressure. A pressure of 20 psig would mean 20 psi gauge, or 20 psi above atmospheric pressure.

Pressure gauges most commonly used in the field by service technicians, to determine pressure within the refrigeration system, are of the Bourdon tube type. As is shown

Figure 11-6 When a vacuum is applied to one side of the manometer, the liquid in that side is forced up and the other side is forced down.

in Figure 11-7, an internal view, the essential element of this type of gauge is the Bourdon tube. This oval metal tube is curved along its length and forms an almost complete circle. One end of the tube is closed, and the other end is connected to the equipment or component being tested.

Figure 11-7 Internal construction of a pressure gauge: (A) adapter fitting, usually a 1/8-in pipe thread; (B) Bourdon tube; (C) link; (D) gear sector; (E) pointer shaft gear; (F) calibrating spring; (G) restrictor; (H) case; (I) cross-section of the Bourdon tube; the dashed lines indicate how the pressure in the Bourdon tube causes it to straighten and operate the gauge.

Figure 11-8 A refrigeration pressure gauge measures pressure above atmosphere pressure.

High-pressure gauges, as shown in Figure 11-8, are preset at 0 lb, which represents atmospheric pressure of 14.7 psi. Any additional pressure applied when the gauge is connected to a piece of equipment will tend to straighten out the Bourdon tube, thereby moving the needle or pointer and its mechanical linkage, thus indicating the amount of pressure being applied. High-pressure gauges can only indicate pressures above atmospheric pressure.

Compound gauges are used to measure pressures above and below atmospheric pressure (Figure 11-9). Pressures below atmospheric are customarily expressed in units of in Hg. There is an indication of the range between 0 gauge and 30 in Hg on the compound gauge.

11.8 ABSOLUTE PRESSURE

Of course atmospheric pressure is not 0; it is approximately 15 psi. Some applications require true, or absolute, pressure. Absolute pressure is simply the real pressure. In absolute pressure, 0 means 0. There is no pressure lower than 0 absolute pressure. Absolute pressure is normally stated in pounds per square inch absolute (psia).

Absolute pressure is the pressure without regard to the current atmospheric pressure. Where atmospheric and gauge pressures may vary from time to time based on when and where they are taken, absolute pressure never changes. The same absolute pressure can give different gauge pressure readings if the gauges used to measure the pressure are calibrated to different atmospheric pressures. For example, a cylinder containing a quantity of refrigerant at a set temperature might have a gauge pressure of 85 psig down at the coast. That same cylinder at the same temperature might only have a gauge pressure of 87 psig in the mountains. However, the cylinder's absolute pressure at both locations would be 100 psia.

Figure 11-9 A refrigeration compound gauge measures pressure above and below atmospheric pressure. (Courtesy of Ritchie Engineering Company, Inc., Yellow Jacket Products Division)

11.9 VACUUM

A vacuum is any pressure less than atmospheric pressure. Mercury columns can be used to measure vacuum by measuring how much pressure has been removed. A pressure of 20 in Hg vacuum means that the pressure is 20 in of mercury less than atmospheric pressure. Since atmospheric pressure is 29.92 in of mercury, a perfect vacuum would be 29.92 in Hg vacuum. This would indicate that all the pressure had been removed. There is no vacuum using absolute pressure because absolute pressure starts with 0 equal to a perfect vacuum. It is impossible to have less pressure than no pressure at all.

Absolute pressure can be used to measure vacuums by measuring how much pressure is left. In the case of a pressure of 20 in Hg vacuum, the absolute pressure would be 9.92 in Hg absolute because 9.92 in of the original 29.92 in of pressure is left. A perfect vacuum using absolute measurement would be 0 in of mercury absolute. This indicates that no pressure remains.

11.10 SI PRESSURE MEASUREMENT

The SI system has a unit made specifically to measure pressure: the pascal. A pascal is equal to a newton per square meter. This is too small a pressure for air-conditioning purposes, so many gauges that read pressure using SI units use kilopascals (kPa). A kilopascal is equal to 1000 pascals. A kilopascal is still a much smaller unit of pressure than psi. A pressure of 100 kilopascals is roughly equivalent to 15 psi. That means that 1 kPa is about one-seventh of 1 psi.

Some metric gauges use bars. A bar is equivalent to 100 kPa and is roughly equal to atmospheric pressure. The bar and barometric pressure both get their names from the same Greek root, *baros*, meaning “weighty.”

11.11 CONVERTING GAUGE AND ABSOLUTE PRESSURES

There are times when it will be necessary to convert between gauge pressure and absolute pressure. Calculating compression ratio is an instance when a service technician will need to convert gauge pressure to absolute pressure. A set of refrigerant gauges shows the system pressure in gauge pressure, but absolute pressures are needed to calculate compression ratio.

Absolute pressure equals gauge pressure plus atmospheric pressure. Use 14.7 if the actual local atmospheric pressure is not known. For most air-conditioning work, the atmospheric pressure can be approximated at 15 psi.

$$\begin{aligned} \text{psia} &= \text{psig} + 14.7 & \text{or} & \quad \text{psia} = \text{psig} + 15 \\ \text{psig} &= \text{psia} - 14.7 & \text{or} & \quad \text{psig} = \text{psia} - 15 \end{aligned}$$

For example, to convert the low side pressure gauge reading of 65 psig to absolute pressure:

$$\begin{aligned} \text{psia} &= \text{psig} + 14.7 \\ \text{psia} &= 65 + 14.7 \\ \text{psia} &= 79.7 \end{aligned}$$

or rounded to

$$\text{psia} = 80$$

To convert a chart reading of 105 psia to the gauge reading you would see in gauge pressure:

$$\begin{aligned} \text{psig} &= \text{psia} - 14.7 \\ \text{psig} &= 105 - 14.7 \\ \text{psig} &= 90.3 \end{aligned}$$

or rounded to

$$\text{psig} = 90$$

SERVICE TIP

Many refrigerant pressure charts and psychrometric charts are based on sea-level readings. You must use the correct chart when working at altitudes that are significantly above sea level. The pressure-temperature chart used by a technician in Denver, Colorado, is going to be different from one used by a technician in Dallas, Texas. If you look at the bottom of the chart, there is often a small note stating the barometric pressure, altitude, or other indications as to the chart's intended use.

11.12 CONVERTING MERCURY COLUMN PRESSURE TO PSI

Standard atmospheric pressure is stated as 14.7 psia or 29.92 in Hg. This means there are approximately 2 in Hg for every psi; 2.04, to be more precise. To convert from inches

Figure 11-10 Mercury manometer.

of mercury to psi, divide inches of mercury by 2.04, or simply use 2 for an easy estimate:

$$\text{psi} = \text{in Hg}/2.04 \text{ or } \text{psi} = \text{Hg}/2 \text{ for an easy estimate}$$

For example, to estimate the psi equivalence for 18 in of mercury, divide 18 by 2 to get 9 psi ($\text{psi} = 18 \text{ in Hg}/2 = 9 \text{ psi}$). For a more precise conversion, divide 18 by 2.04 ($18/2.04 = 8.8 \text{ psi}$).

To convert from psi to inches of mercury, simply multiply by 2.04 for precision, or by 2 for a quick estimate. For example, 8 psi would be 16.32 in of mercury ($8 \times 2.04 = 16.32$).

Most positive mercury column measurement is absolute. One end of the tube that the mercury is in is sealed, and the space between the mercury and the sealed end of the tube is in a vacuum (Figure 11-10). When converting gauge pressure, psig, to mercury column pressure absolute, the gauge pressure should first be converted to absolute pressure, psia.

11.13 VACUUM CONVERSIONS

Sometimes vacuums are measure by how much pressure has been removed, as in inches of mercury vacuum, and sometimes the vacuum is measured by how much pressure is left, as in inches of mercury absolute. To convert between the two, subtract the value you want to convert from 29.92. You can use 30 for a very close estimate. For example, an 18 in Hg vacuum is approximately 12 in Hg absolute. Subtracting either one from 30 will produce the other: $30 - 18 \text{ in Hg vacuum} = 12 \text{ in Hg absolute}$; $30 - 12 \text{ in Hg absolute} = 18 \text{ in Hg vacuum}$.

SERVICE TIP

Parts of low-pressure refrigeration systems operate in a vacuum. Some manufacturers specify their pressures in psia, while others specify their pressures in inches Hg vacuum. For a close estimate of psia from inches Hg vacuum, first subtract the inches of Hg vacuum from 30, and then divide the answer by 2. In the case of 16 in Hg vacuum:

$$30 - 16 = 14$$

$$14/2 = 7 \text{ psia}$$

For more precision, use 29.92 and 2.04:

$$29.92 - 16 = 13.92$$

$$13.92/2.04 = 6.8 \text{ psia}$$

11.14 FLUID PRESSURE

A fluid is a substance that deforms and flows under pressure. Fluids change shape and move from one point to another because of pressure difference. Both liquids and gases are considered fluids because both can take the shape of their container and can flow from one place to another because of pressure difference. Like all matter, fluids have weight—even gases.

The weight of any solid material acts as a downward force on whatever is supporting it. The force of a solid object is the overall weight of the object, which is distributed over the area on which it lies. The weight of a given volume of water, however, acts not only as a force downward on the bottom of the container holding it but also as a force laterally on the sides of the container. If a hole is made in the side of the container below the water level, as in Figure-11-11, the water above the hole will be forced out because of its force acting downward and sideways.

Figure 11-11 Water exerts pressure on the sides and bottom of its container.

TECH TIP

The most commonly overlooked fluid that affects air-conditioning performance is air. Many people do not realize that air is a fluid. However, either a liquid or a gas can be a fluid because a fluid is anything that can flow. That makes air a fluid with all of the associated characteristics of weight, density, inertia, and pressure.

Fluid pressure is the force per unit area that is exerted by a gas or a liquid. Fluid pressure varies directly with the density and the depth of the fluid. At the same depth below the surface, the pressure is equal in all directions. Notice the difference between the terms used: *force* and *pressure*. Force means the total weight of the substance; pressure means the unit force or pressure per square inch.

The tank in Figure 11-11 measures 1 ft in all dimensions and holds exactly 1 ft³ of water. The weight of 1 ft³ of water is approximately 62.4 lb; therefore, the total force being exerted on the bottom of the tank is 62.4 lb. The force is spread over an area of 144 in² (12 in × 12 in = 144 in²). Using the equation

$$\text{Pressure} = \frac{\text{Force}}{\text{Area}}$$

a pressure of 0.433 psi is exerted on the bottom of the tank (62.4/144 = 0.433).

11.15 HEAD PRESSURE

Pressure and depth have a close relationship when a fluid is involved. The head is the height of water expressed in feet and is used to express water pressure in a system. Water pressure varies directly with its depth. As an example, if the tank in Figure 11-11 was 2 ft high and filled with water, it would contain a volume of 2 ft³ of water and would weigh 2 × 62.4 lb, or 124.8 lb. Now the force of the water on the bottom of the tank would still be distributed over 144 in² and the unit pressure would be 0.866 psi (124.8 lb ÷ 144 in²). This is twice the amount of pressure that was exerted when the head of water was only 1 ft. Therefore, in an open-top container, the pressure of the water will equal 0.433 psi for each foot of head.

SERVICE TIP

A pump only moves fluid; it does not create pressure. The resistance to the flow of a fluid is what results in pressure. A pump that has a fully unrestricted outlet will have zero or nearly zero pressure reading. It is only when a pipe is attached to the outlet and the water directed through the pipe or up some distance that the pressure in the system is created.

The same relationship follows when pumping water in a system. The head is the height difference from the lowest point to the highest point. An increase in the height

Figure 11-12 Gas exerts force evenly against all sides of its container.

that a pump must move the water increases the pressure. The head pressure can be determined by multiplying 0.433 times the height. If the height is 10 ft, the pressure will be 0.433×10 , or 4.33 psi.

The tank in Figure 11-11 has an area of 1 ft² with 1 ft of head; therefore, the pressure on the bottom of the tank is 0.433 psi. If there is a fish pond covering an area of 50 ft², and the depth of water in it is 1 ft, the pressure on the bottom of the pond will still be just 0.433 psi, even though there is a larger total volume of water. The pressure is determined by the depth of the water, not the volume.

11.16 GAS PRESSURE

An ideal gas is one in which the molecules of the gas have no attraction for each other. An important characteristic of an ideal gas is that it will expand to take up the entire volume that it is contained in. When gas is confined, it pushes against the sides of its container, creating pressure (Figure 11-12). This pressure is created by the kinetic energy of the gas molecules as they strike the surface of the container. If more molecules are put into the same container, the pressure goes up because now there are more molecules to strike the surface (Figure 11-13).

Figure 11-13 Increasing the number of gas molecules in the container increases the pressure on the sides of the container.

TECH TIP

Nitrogen is stored as a compressed gas in cylinders at very high pressures. The pressures are high because so much nitrogen gas is stuffed into the cylinder. Immediately after the cylinders are filled, the pressure is as high as 2,400 psig. As nitrogen is used out of the cylinder, the cylinder pressure decreases because there is less nitrogen in the cylinder.

If the temperature of the gas is increased, the increased speed and kinetic energy of the molecules increases the number of times molecules strike the surface and increases the pressure. If the volume of the container is reduced, the pressure increases because the molecules are packed in more closely and strike the surface more often. Therefore, the three ways that gas pressure can be increased are by increasing the quantity of gas in the container, increasing the temperature of the gas, or decreasing the size of the container. Naturally, these all work in reverse as well: gas pressure can be reduced by removing some of the gas from the container, decreasing the gas temperature, or increasing the size of the container.

11.17 GAS LAWS

Many scientists have studied the behavior of gases and contributed to our knowledge of gas laws. Several scientists have published their findings demonstrating a particular aspect of gas behavior. The math formulas describing the particular gas behavior they studied have become known as the gas laws. Each law is named after the scientist credited with creating it. The laws governing gas behavior are summarized in the list below.

- **Pascal's law** Pascal's law states that gas pressure is exerted uniformly everywhere on its container.
- **Boyle's law** Boyle's law states that pressure increases as volume decreases.
- **Charles's law** Charles's law states that volume increases as temperature increases.
- **Gay-Lussac's law** Gay-Lussac's law states that the pressure increases as the temperature increases.
- **Ideal gas law** The ideal gas law is a combination of all of these laws and describes the behavior of gases.
- **Dalton's law** Dalton's law states that the total pressure of a mixture of gases is equal to the sum of their individual pressures.

Absolute Pressure and Temperature

All pressures and temperatures must be converted to absolute temperatures and pressures before attempting to solve any of the equations because the gas law formulas only work for absolute temperature and absolute pressure. This is because ratio and proportion will not give correct results for any system that uses both positive and negative values. Absolute temperature and absolute pressure have no negative numbers. The coldest temperature on an

Figure 11-14 Pascal's law states that gas pressure is applied evenly on all surfaces of the container holding the gas.

absolute scale is 0°; there are no negative temperatures. The lowest pressure on an absolute pressure scale is 0; there is no vacuum.

11.18 PASCAL'S LAW

Pascal's law describes how a gas reacts in a confined space. Pascal's law states that when a gas is confined, it exerts equal pressure in all directions. This means that if the pressure were measured from the outside or inside or from the top or bottom, the pressure readings would all be the same (Figure 11-14).

11.19 BOYLE'S LAW

Boyle's law describes the relationship between the volume and pressure of a gas. Boyle's law states that the volume of a gas varies inversely with its pressure if the temperature of the gas remains constant. This means that if the volume increases, the pressure will decrease. For example, if the volume of a gas is doubled, the pressure will be halved. This also works the other way: when the volume decreases, the pressure increases. If the volume is halved, the pressure is doubled. This is the operating principle of compressors. Figure 11-15 shows a fixed quantity of gas before and after being compressed.

11.20 CHARLES'S LAW

Charles's law describes how a gas volume reacts to changes in temperature. Charles's law states that the volume of a gas is in direct proportion to its absolute temperature, provided that the pressure is kept constant. This means that a gas will expand in volume with an increase in temperature and contract in volume with a decrease in temperature. Figure 11-16 shows a balloon at two different temperatures. When the

Figure 11-15 Confining the same number of gas molecules in a smaller space increases the gas pressure.

Figure 11-16 The same number of gas molecules take up more space at a higher temperature.

gas in the balloon is at a higher temperature, the gas volume expands, making the balloon larger.

TECH TIP

The increase in gas volume that accompanies an increase in gas temperature is the operating principle of hot-air balloons. The heated air inside the balloon expands, making it less dense than the surrounding air.

11.21 GAY-LUSSAC'S LAW

Gay-Lussac's law describes the relationship between gas pressure and gas temperature: the pressure of a gas is directly proportional to its temperature with the volume remaining constant. This means that increasing the temperature increases the pressure, or decreasing the temperature

Figure 11-17 With the same number of molecules and the same amount of space, the container with the higher temperature will have a higher pressure.

will decrease the pressure. Figure 11-17 shows two identical volumes of gas at different temperatures. The volume at a higher temperature is also at a higher pressure.

11.22 IDEAL GAS LAW

A combination of all of the above laws is called the ideal gas law. All of the previous relationships assumed that one of the variables remained constant. In reality, this is seldom the case. The ideal gas law makes predictions of gas behavior possible even when all of the variables are changing. Mathematically, the ideal gas law may be written as

$$P_1 V_1/T_1 = P_2 V_2/T_2$$

where

V_1 = the starting volume

V_2 = the ending volume

P_1 = the starting pressure

P_2 = the ending pressure

T_1 = the starting temperature

T_2 = the ending temperature

The basic formula can be rearranged to show the solution for new volume, new pressure, or new temperature:

New volume

$$V_2 = (T_2 \times V_1 \times P_1) \div (T_1 \times P_2)$$

New pressure

$$P_2 = (T_2 \times V_1 \times P_1) \div (T_1 \times V_2)$$

New temperature

$$T_2 = (T_1 \times V_2 \times P_2) \div (V_1 \times P_1)$$

Just plug in the relevant numbers to solve for new volume, new pressure, or new temperature. When working a problem that does not use all three variables, just leave off the variable you are not using. For example, to solve for new

pressure when the volume remains constant, the formula becomes

$$P_2 = (T_2 \times P_1) \div T_1$$

11.23 GAS LAW EXAMPLE PROBLEMS

A few practical applications of the ideal gas law will illustrate how these formulas work.

Standing Leak Test

A refrigeration system is charged with nitrogen to check for leaks. The temperature of the system and surroundings is 100°F when the system is charged to 100 psig. The pressure is checked the following morning after the temperature has dropped to 50°F. The pressure will have dropped slightly even if no nitrogen has escaped. What should the pressure be if no nitrogen has escaped?

The formula to use is

$$P_2 = (T_2 \times V_1 \times P_1) \div (T_1 \times V_2)$$

Since the space in the system, the volume, is staying the same, this can be shortened to

$$P_2 = (T_2 \times P_1) \div T_1$$

Convert the pressures and temperatures to absolute.

$$100 \text{ psig} + 15 = 115 \text{ psia}$$

$$100^\circ\text{F} + 460 = 560^\circ\text{R}$$

$$50^\circ\text{F} + 460 = 510^\circ\text{R}$$

Plug the numbers into the formula.

$$(510^\circ\text{R} \times 115 \text{ psia}) \div 560^\circ\text{R} = 105 \text{ psia}$$

Convert 105 psia to psig.

$$105 \text{ psia} - 15 = 90 \text{ psig}$$

Compressed Gas

What would be the final volume of 4 ft³ of gas that is compressed from 60°F at 70 psig to 150°F at 210 psig?

Since everything is changing, the formula to use is

$$V_2 = (T_2 \times V_1 \times P_1) \div (T_1 \times P_2)$$

Convert the pressures and temperatures to absolute.

$$70 \text{ psig} + 15 = 85 \text{ psia}$$

$$210 \text{ psig} + 15 = 225 \text{ psia}$$

$$60^\circ\text{F} + 460 = 520^\circ\text{R}$$

$$150^\circ\text{F} + 460 = 610^\circ\text{R}$$

Plug the numbers into the formula.

$$V_2 = (610^\circ\text{R} \times 4 \text{ ft}^3 \times 85 \text{ psia}) \div (520^\circ\text{R} \times 225 \text{ psia})$$

$$V_2 = 1.8 \text{ ft}^3$$

Compressed Air Cooling

One of the more interesting air-conditioning systems that have been developed works by compressing and expanding air. Air is compressed, raising its pressure and temperature. It is then cooled to outdoor ambient temperature by passing it through a cooling coil. Finally, the compressed air is passed through an orifice where its pressure is dropped and it is expanded back to its original volume, but with less heat. Calculate the leaving air temperature of a system that is expanding air from 5 ft³/lb at 30 psig and 100°F to a new volume of 14 ft³ at 0 psig.

Since everything is changing, the formula to use is

$$T_2 = (T_1 \times V_2 \times P_2) \div (V_1 \times P_1)$$

Convert the pressures and temperatures to absolute.

$$30 \text{ psig} + 15 = 45 \text{ psia}$$

$$0 \text{ psig} + 15 = 15 \text{ psia}$$

$$100^\circ\text{F} + 460 = 560^\circ\text{R}$$

Plug the numbers into the formula.

$$T_2 = (560^\circ\text{R} \times 14 \text{ ft}^3 \times 15 \text{ psia}) \div (5 \text{ ft}^3 \times 45 \text{ psia}) = 523^\circ\text{R}$$

Convert 523°R to °F.

$$523^\circ\text{R} - 460 = 63^\circ\text{F}$$

11.24 DALTON'S LAW

Dalton's law states that the total pressure of a gas mixture is equal to the sum of all the gas partial pressures in the mixture. This means the total pressure of a mixture of gases can be determined by adding each of the individual gas pressures (Figure 11-18). Dalton's law is a logical extension of Avogadro's law, which states that equal volumes of gases, at the same temperature and pressure, contain the same number of atoms or molecules. The type of the gas has no effect on the gas pressure, only the number of molecules in the container.

TECH TIP

In the field, you can easily check to see whether a cylinder of refrigerant is contaminated with air. If a cylinder of refrigerant is contaminated with air, the pressure gauge reading will be equal to the reading for the refrigerant and the air added together. Take the cylinder's pressure and temperature, and compare the results to a refrigerant chart. If the pressure you obtained is higher, the cylinder contains something other than pure refrigerant, and that is usually air.

11.25 SATURATED GAS

So far, all the discussion has related to the behavior of an ideal gas in which the molecules have no attraction for one another. However, when a gas is at the saturation point,

Figure 11-18 When two separate gases are put in the same container, the total pressure in the container is the sum of the individual pressures.

the molecules have enough attraction for each other that removing heat from them will cause them to condense to a liquid. A saturated gas behaves very differently from an ideal gas because the gas can change state at the saturation point. For this reason, saturated gases do not follow the ideal gas laws.

The temperature and pressure changes of a saturated mixture are far greater than those of an ideal gas. Adding heat to a saturated mixture in a container creates more gas molecules while leaving the volume the same. More gas molecules create more gas pressure. This increase in pressure is much more dramatic than the increase in pressure due to simply increasing the temperature of the molecules that are already there, as in an ideal gas.

UNIT 11—SUMMARY

Hydronic, pneumatic, refrigeration, and air systems all depend upon pressure differences to create flow. That is why HVACR technicians must be familiar with pressure and vacuum readings so they can properly install, service, and repair these systems.

Absolute pressure is the only pressure reading that is not dependant on the surrounding atmospheric pressure. Absolute pressure is not often used by the HVACR field technician, but it is important to know about and may be a factor in some refrigeration applications. For example, low-temperature refrigeration often operates in a vacuum. As you now know, the total pressure difference between an absolute vacuum and atmospheric pressure is 14.7 psi. That is not very much pressure to work with as compared to air conditioning that might have 300–400 psi. Therefore, in some low-temperature refrigeration service, technicians may have to convert gauge reading to absolute to know exactly how the system is working and at what temperature.

UNIT 12

Calibrations of Meters and Instruments

OBJECTIVES

After completing this unit, you will be able to:

1. use the correct terminology when talking about instrument calibration.
2. perform simple procedures to verify the calibration of temperature-measuring instruments.
3. demonstrate that pressure readings are within tolerance.
4. verify the proper operation and accuracy of leak-detection instruments.
5. perform calibration-verification checks of flue-gas analysis instruments.

12.1 INTRODUCTION

Instruments are calibrated for several reasons, including ensuring improved troubleshooting accuracy and that a system is working according to design specifications. If the instruments the technicians use are not calibrated and are not providing accurate information, it will be difficult to make a determination of actual equipment performance. Many commercial buildings and some residential homes are now being commissioned. Commissioning is the process of testing all the building's systems and certifying to the owner that they are all operating according to the manufacturer's specifications. To commission a system or building, technicians must be using instruments that are calibrated.

12.2 CALIBRATION

Calibration is a baseline testing and adjustment procedure performed on instruments to ensure that the measured indication or output is an accurate representation of the process. The technician may calibrate some instruments, and others may need to be sent to a meter shop to be calibrated.

The instrument manufacturer may specify how often an instrument must be calibrated. In some cases, local codes may require some critical instruments to be calibrated and recertified on a regular schedule. The instrument used to certify the calibration of your instrument will have its calibration traced back to the National Institute of Standards and Technology. Certified calibrated equipment will have a sticker listing who performed the calibration, the date of the calibration, the date the calibration expires, and any error factor that must be used to correct the instrument's reading (Figure 12-1).

Not all instruments can be calibrated. Some electronic instruments cannot be calibrated but must be tested periodically to ensure that they are working accurately. If they are found to be out of calibration beyond the acceptable limits, they must be replaced.

SERVICE TIP

The meter movement on many analog meters is very sensitive. In some cases the weight of the instrument needle can affect the reading. The needle's weight is less when the meter is laying flat as compared to when it is set upright.

The faceplate is typically made of plastic (not glass) to provide a more robust instrument capable of handling the rough environment and conditions to which it may be exposed. Static electricity on the plastic faceplate can affect the reading. To test for static buildup on the plastic face, slowly wave your hand over the top of the faceplate without actually touching it. If the indicator needle moves, static is present. The static electricity can be removed using an anti-static spray available from either the manufacturer or a supply house.

Calibration Terminology

Accuracy Accuracy is how exact a device is when making a measurement. An example is a meter measuring a conductor carrying 100 V. If the meter is 100 percent accurate, it indicates exactly 100 V with no tolerance. Highly accurate instruments are those used in a laboratory environment.

Range The range is the difference between the smallest indication on the scale and the largest indication on the scale. When talking about an instrument with a 0 percent reading of 4 mA and a 100 percent reading of 20 mA, the range is 16 mA.

Span The span is the value that represents 100 percent of the scale of an instrument. When talking about an instrument with a range of 4 mA to 20 mA, the span is 20 mA.

Tolerance The tolerance is the amount of variation allowed from a standard. Typically tolerance is expressed in percent (%). Your digital volt-ohmmeter

TECH TIP

"Standard atmospheric pressure" is based upon conditions at sea level, and this is typically taken to be 14.7 psi. However, depending on your geographic location, atmospheric pressure will be different. In Denver, Colorado, often referred to as being a "mile high," the atmospheric pressure is only slightly above 12 psi.

To perform an operational check on any temperature-sensing device, it must be subjected to a known temperature. An easy way to generate a known temperature is to use water and apply heat. Water boils at 212°F and freezes at 32°F at standard atmospheric pressure. These are two easily duplicated temperatures. If the heat-sensing portion (tip) of the temperature-sensing device is placed in boiling water, it should generate a reading of 212°F at standard atmospheric pressure, and in an ice/water bath it should read between 32°F and 33°F. Ice water is never exactly 32°F due to the heat flow from a warmer substance, the water, to a cooler substance, the ice. For most shop calibrations of temperature-sensing devices, this is within the acceptable level of accuracy.

Not all equipment can be immersed in water, and sometimes temperatures higher than 212°F are required for calibration. For these instruments, a sand bath can be used. A sand bath is a container full of sand. It is surrounded by an electric heating element. To increase the temperature, the electricity to the heating element is increased. To decrease the temperature, the electricity going to the heating element is decreased. Air is slowly forced up from the bottom of the container to ensure that the temperature is constant in the bath. As you might expect, the time required to perform this type of calibration is prolonged. It takes a while for the mass of the sand in the container to both heat up and cool down. A certified test instrument measures the temperature of the sand.

A third method to provide heat is the use of an oven. Varying the electricity applied to the heating elements varies the temperature in the oven. A certified instrument indicates the temperature inside the oven.

Resistance Thermal Devices (RTDs)

Resistance thermal devices provide an output in units of ohms or resistance. These are devices that change their resistance according to how much temperature they are sensing. They are manufactured to measure within specific temperature ranges. To verify their correct operation, we need the manufacturer's chart and an ohmmeter. If we subject the RTD to a known temperature, we can refer to the manufacturer's chart and see how much resistance the RTD should be generating. You can then measure the resistance and determine if the RTD is operating correctly.

To perform a calibration check of the RTD, it must be subjected to known temperature values at 0%, 25%, 50%, 75%, and 100% of its range. By measuring the resistance

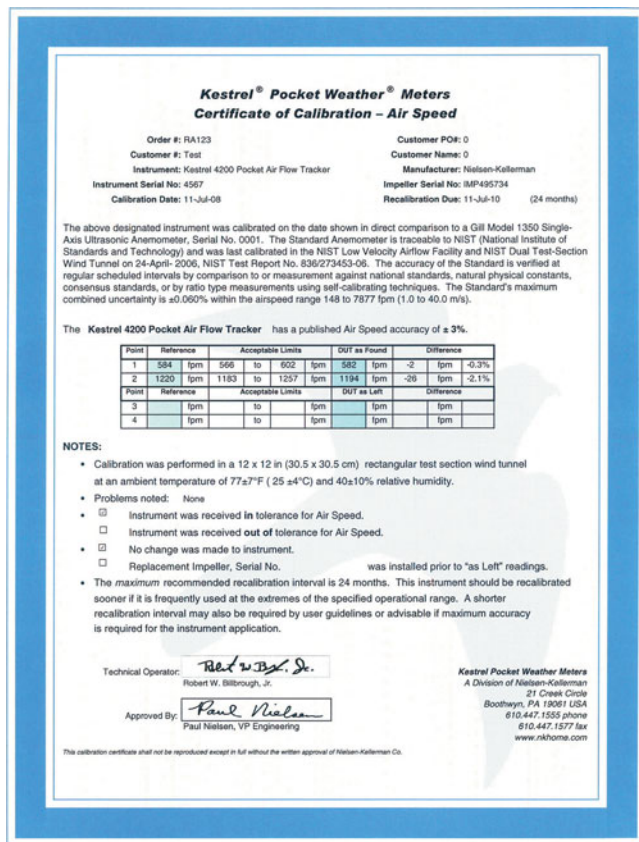

Figure 12-1 Instrument-calibration sticker with test data, expiration date, and error factor. (Courtesy of Nielsen-Kellerman)

may have a tolerance of ± 1 percent. What this means is that if a conductor is carrying 100 V, the meter may indicate anything from 99 V to 101 V and still be within tolerance. If the meter indicates 98.9–101.1 V, it is out of tolerance and requires calibration.

Zero Zero is the value that represents 0 percent of the range of an instrument. It is not necessarily 0. Zero, when talking about an instrument with a range of 4 mA to 20 mA, is 4 mA. As an example, a refrigerant gauge may read zero, but that only means the gauge pressure is zero; it does not mean there is no atmospheric pressure.

12.3 TEMPERATURE-MEASURING INSTRUMENTS

There are a number of ways that temperature-measuring instruments may sense temperature. Some, like resistance thermal devices (RTDs), change their electrical resistance with changes in temperature. Thermocouples provide varying voltages with temperature changes. In contrast, a bimetallic device produces mechanical changes that are translated to a dial.

generated at these values and comparing them to the information provided on the manufacturer's chart, you can determine whether the RTD is working properly. The technician records the resistance-to-temperature relationships on an instrument data sheet. The technician cannot adjust an RTD. If the unit is out of tolerance, it cannot be used, and a new one will have to be obtained. Even if a new RTD is being used, its accuracy must be checked/verified using the previously mentioned procedure.

RTDs come in two types: negative temperature coefficient (NTC) and positive temperature coefficient (PTC). In the case of an NTC, the resistance increases as the temperature decreases. In the case of a PTC, the resistance increases as the temperature increases. These types of devices are often used in residential refrigerators and freezers and as temperature-measuring instruments and sensors installed in equipment utilizing an electronic circuit for control.

Thermocouples

Thermocouples generate a millivoltage (mV) of electrical power when heated. The millivoltage generated for each degree of temperature differs depending on the makeup of the thermocouple wires. Refer to the manufacturer's data sheet to see what the millivoltage output should be for the thermocouple you are testing. Due to length of thermocouple wire or other factors, thermocouple readings may vary slightly. Checks should be made at 0%, 25%, 50%, 75%, and 100% of the required range. The millivoltage output of the thermocouple at these points is recorded on the instrument data sheet and compared to the required tolerance as specified by the manufacturer.

The thermocouple reading may deviate by a degree or two. Often technicians will write the degree of deviation on the thermocouple lead, instructing the user to correct the reading they obtain by adding or subtracting 1° or 2° from that reading.

The hot junction is typically the point where thermocouples fail. The connection comes apart. Once the connection is broken, it cannot be soldered back together. Therefore, we cannot repair thermocouples. Devices such as these can be measured for accuracy using a multifunction process calibrator, as shown in Figure 12-2.

Bimetallic Devices

Bimetallic devices provide a visual indication of temperature, such as an analog thermostat connected to a residential heating/cooling system. A scale is labeled to indicate the temperature that the device is sensing.

Factors that affect the accuracy of this device are the graduations of the scale and the consistency of the expansion/contraction rate of the metals used. Both of these factors are a function of their initial construction at the manufacturer's facility and are beyond the control of the technician. On spiral-type bimetallic springs, a small screwdriver can be used to adjust the temperature pointer upward or downward if its reading is not correct. On conical bimetallic-type instruments, like a dial pocket thermometer, a small wrench can be used to hold the stem while the dial is turned so the pointer is directed at the correct temperature. Repeated rotating or twisting of these conical,

helical, or coil-wound devices will distort them and render the reading meaningless.

A reading that is off by as much as 5 to 7 percent is not uncommon for these types of instruments. For this reason, most temperature-measuring instruments today are digital. Figure 12-3 shows a digital pocket thermometer.

12.4 PRESSURE-MEASURING INSTRUMENTS

Pressure gauges can be electronic or mechanical. In most cases, electronic pressure sensors cannot be calibrated. They can be tested against a known pressure, and, if their reading falls within the acceptable range, they can be used, but if they are found to be out of tolerance, they must be replaced.

The mechanical gauges like the ones on a refrigerant manifold test set may have a small adjusting screw on the gauge face (Figure 12-4). There are two ways this screw can be adjusted. One is to adjust the needle to the 0 psi point. The other method is to attach the gauge to a known pressure source and adjust the needle to point at that pressure. One possible pressure source would be a source attached to a certified pressure gauge. A certified source like this can be adjusted to make sure the gauge reads accurately all the way across the scale. A second way to set the gauge is to attach it to a nearly full new refrigerant cylinder that has a stable measured temperature. Compare the temperature of the refrigerant to the gauge reading and adjust the needle as required.

SERVICE TIP

A full or nearly full refrigerant cylinder is required because attaching the gauge can cause a significant pressure drop in cylinders containing small quantities of refrigerant.

12.5 VACUUM-MEASURING INSTRUMENTS

U-shaped vacuum instruments have a moveable scale that when attached looks much like a ruler (Figure 12-5). This scale is adjustable in that it has the ability to slide up and down in relationship to the tube. This scale reads in inches of water, sometimes expressed as WC (water column) or inches of mercury, expressed as inches Hg. The scale has a 0 in the middle and goes to plus reading (positive pressure) and a minus reading (vacuum).

Typical values are plus 10 inches to minus 10 inches, but this can vary depending on the range of the instrument.

Figure 12-5 U-tube manometer. (Courtesy of RadonAway Inc.)

Water-filled U-shaped vacuum instruments use distilled water. Since distilled water is clear and hard to see against a scale, a dye is added to change the clear water to a green, blue, or red liquid. This makes it much easier to see. Once the colored water is poured into the tube, the calibration process can be performed. Simply slide the scale up or down until the 0 on the scale is perfectly lined up with the water level in the tubes. That is all the technician can do.

SERVICE TIP

The distance the water moves when vacuum is applied is a function of the water's specific gravity, and the indication on the scale is a function of the accuracy of the scale's manufacturer. Since a fixed specific gravity of the water is necessary for accurate readings, it is important to use only the special dye designed for this purpose. If you were to use food coloring, for instance, it would change the specific gravity of the water, resulting in inaccurate readings.

A variation of this instrument is a tube filled with mercury. Its operating principle and method of calibration are identical to the water-filled tube. This instrument reads out in inches or millimeters of mercury (in/mm Hg). This instrument is not used much in the field because of the chance of spilling the mercury, which is a dangerous (and expensive) consequence. Mercury spillage/contamination is an Environmental Protection Agency (EPA) reportable situation, and extreme care should be exercised in its use and disposal (Figure 12-6).

Analog Electronic Vacuum Instruments

Analog electronic vacuum instruments are both easy to use and to calibrate. They are powered by electrical energy and convert vacuum to a reading on a scale through the use of a transducer. The units on scale are microns.

The unit has a scale and a switch, and the switch has two positions. One position is labeled ON or READ, and the other position is labeled CALIBRATE. The calibration procedure requires a number of steps. First, take a close look at the transducer. It is a metal tubular device with an electrical cord coming out of one end and a threaded connector on the other end. The electrical cord is connected to the main body of the instrument. The threaded connector is used to facilitate the connection of a hose that is connected to the system on which vacuum readings are being taken (Figure 12-7).

As you perform a closer visual inspection of the transducer, you will notice a number stamped into its case. Although there is no standard number, a typical number would be 30.25. Before connecting the transducer to the system being measured, place the unit in the ON position. Now observe the number stamped into the transducer. Say it is 30.25. Place the switch into the CALIBRATE position. There will be an adjustment knob on the main body of the instrument. Adjust this knob until the needle indicates the value stamped into the transducer, in this case 30.25. Place the switch into the READ position. The instrument is now ready for use.

Managing Hazardous Waste

1. Identify

If you don't know if a specific waste is hazardous, check label(s) or MSDS to determine if these criteria apply:

Toxic:

- ✓ carcinogen,
- ✓ bioaccumulative properties,
- ✓ waste containing heavy metals/organics
- ✓ waste oil

Corrosive:

- pH < 2 or >12.5

Ignitable:

- Liquids with a flash point of $\leq 140^{\circ}\text{F}$ (60°C)
- Solids that burn spontaneously
- Oxidizers

Reactive:

- ✓ Unstable material
- ✓ Explosives
- ✓ Water reactivities
- ✓ Cyanide or sulfide-bearing wastes

Figure 12-7 Analog electronic vacuum instrument transducer.
(Courtesy of SPX Corporation)

There is one consideration with this type of instrument. Be careful not to expose the transducer itself to oil or liquid refrigerant. This contamination will render the transducer useless and another one will have to be obtained.

Digital Electronic Vacuum Instruments

There is no user calibration required on digital electronic vacuum instruments. Calibration has been performed by the manufacturer and will last the life of the instrument.

12.6 ELECTRICITY-MEASURING INSTRUMENTS

Electronic instruments such as volt meters, ohm meters, and ammeters, along with wattmeters, power meters, and phase angle meters, may be out of calibration. If the readings provided are not within tolerance, these instruments must be returned to the manufacturer for calibration. There are no user level adjustments that can be made, and, typically, even removing the cover to gain access to the circuit board will void the warranty.

12.7 REFRIGERANT LEAK-DETECTION INSTRUMENTS

Analog Leak Detectors

Analog detectors have a small sensing wand connected to the main body of the instrument. This sensing wand is

used to “sniff” along the system tubing/piping in its entirety. There is a small pump in the body of the instrument. There is usually a small filter at the end of the sensing tube that should be changed before calibration begins.

It is important to note that the sensing tips of these wands should never come in contact with refrigerant. If they are exposed to refrigerant, they must be replaced. There is little that can be adjusted other than using a small screwdriver to adjust the meter movement for a zero reading. Calibration of the most complex leak-detection instruments is beyond the scope of the technician. These instruments must be returned to the manufacturer, where the calibration can be performed in an instrument-calibration laboratory.

To perform a calibration-verification procedure, test gases of 0 and 100 percent concentration must be purchased. These are available from the manufacturer and some supply houses. First, the sensor is exposed to a gas with no refrigerant or zero concentration. At this point, the minimum or zero indication is adjusted mechanically by slightly rotating a limit screw on the face of the meter or electronically by carefully adjusting a potentiometer on the circuit board to a value specified in the manufacturer's calibration procedures. Next, the sensor is exposed to a gas of 100 percent concentration. At this point there are no mechanical adjustments, electronic only. Access to the circuitry inside is required, and a potentiometer must be adjusted to provide the voltage recommended by the manufacturer or until a 100 percent maximum (span) reading is indicated on the meter. With all mechanical 0 percent (zero) and electronic 100 percent (span) adjustments, one adjustment affects the other. This requires you to go back and check 0 percent again because it will be off just a bit. Then recheck the 100 percent adjustment. Continue checking both the minimum and maximum indications until both are accurate. Electronic adjustments are not so inter-related, but it is good practice to check 0 percent and 100 percent several times to ensure both are correct.

Digital Leak Detectors

These detectors have some of the same limitations as the analog models. Exposing the wand sensing tips to refrigerant renders them useless. These types of instruments have removable/replaceable tips that can be installed if needed. They operate on a slightly different principle from the analog units. Digital instruments do not draw in an air sample. They measure the conductivity between two sensor plates. Clean air provides less conductivity as compared to air with refrigerant in it. The amount of difference in conductivity is the input, which is then converted into audible signals via microprocessors or integrated circuits.

Given this principle of operation, it should be understandable that these instruments are more effective in enclosed spaces as compared to operating on the roof of a building with the wind blowing. There is no calibration on these instruments that the technician can perform. You can verify operation by first purposely exposing the wand tip to a refrigerant source and listening for the audible indication. Next, proceed to a location where there is no refrigerant, and no audible detection signal should be heard.

12.8 FLUE GAS ANALYSIS INSTRUMENTS

The newer types of instruments have a small pump built into them. Like their predecessors, they must be inserted into the flue pipe, but its location is not as critical. When the sensing tip is inserted, the technician initiates the test. The small internal pump takes an air sample for X amount of seconds and electronically performs an analysis of the gases it has drawn in. A digital display is provided, although attachments can be purchased that provide a printout of the results. The newer types of instruments perform many tests on the exact same sample of flue gas. This helps eliminate an inaccurate reading caused by the improper placement of the sensing tip. The calibration of this type of instrumentation varies according to functionality.

Analog Flue Gas Instruments

For analog flue gas instruments, compensation must be made for the condition of the batteries in the unit. When batteries are new, they provide more voltage and current than older batteries. This can affect instrument readings. You must also compensate for the temperature of the batteries. Even with new batteries, the amount of voltage and current provided varies with the temperature. Colder batteries provide less voltage and current than warmer batteries. Placing a selector switch to the BATT (or CAL) position and adjusting a knob for the desired indication on the faceplate will compensate for both of these battery conditions.

Digital Flue Gas Instruments

Unlike their analog counterparts, digital displays are not affected by static electricity. The condition of the batteries is not as important either. Usually, digital display models will continue to operate with the advertised accuracy until a LOW BATT icon is displayed. There is also no zeroing of the display required.

Calibration Verification of Flue Gas Instruments

The calibration verification of both types of these instruments is accomplished in the same way. Sample gases must be purchased from the manufacturer of the instrument. The sensing tip is then exposed to these gases and an indication provided.

If the indication is within tolerance, calibration verification is complete and no further action is required. If the indication provided is not within tolerance, the instrument must be returned to the manufacturer for calibration. There are no user level adjustments that can be made, and typically even removing the cover to gain access to the circuit board will void the warranty.

UNIT 12—SUMMARY

Technicians use a variety of electronic instruments to provide an accurate picture of exactly how a specific HVACR system is performing. Most of these parameters cannot be visually observed, so the use of instrumentation is required.

It is the responsibility of the technician to determine whether the electronic instruments are operating correctly. If the instruments are not operating correctly, the faulty measurement could waste the technician's valuable time when troubleshooting a condition that does not exist or, even worse, cause the technician to miss a condition that needs to be rectified.

Manufacturer-level calibration is available for a fee, and expedited work for an increased fee is available from some manufacturers. This service is one that should be considered when initially purchasing your particular instrument.

Types of Refrigeration Systems

OBJECTIVES

After completing this unit, you will be able to:

1. define *refrigeration*.
2. list the different types of cooling systems.
3. explain the fundamental principles of evaporative cooling.
4. explain the basic operation of thermoelectric refrigeration.
5. explain the fundamental principles behind the compression-refrigeration cycle.
6. discuss the difference between the compression cycle and the absorption cycle.

13.1 INTRODUCTION

The purpose of any refrigeration system is to move heat. Typically the heat is being moved from a place where it is not wanted to a place where it is unobjectionable. Most often this involves moving heat from a cool place to a warmer place. Pushing heat uphill like this requires energy. There are many types of cooling systems, including absorption, evaporative, thermoelectric, and mechanical compression. The different types of refrigeration systems differ in how they accomplish this task, but they all involve using energy to move heat. The mechanical compression-refrigeration cycle is by far the most common. The mechanical compression-refrigeration cycle is applied in air conditioning, commercial refrigeration, and industrial process refrigeration. Air-conditioning systems cool people. They use refrigeration to provide comfort cooling and dehumidification in residential and commercial buildings (Figure 13-1). Commercial refrigeration systems are chiefly concerned with cooling products. Commercial refrigeration systems can be found in grocery stores, restaurants, refrigerated warehouses, and science labs (Figure 13-2). Industrial process refrigeration is used to cool equipment and machinery in large industrial manufacturing plants (Figure 13-3).

Figure 13-2 Commercial refrigeration unit.

GREEN TIP

The heat being moved can often be used. For example, heat rejected by an air-conditioning system can be used to heat hot water. Using the heat that is removed from the area being cooled to heat domestic hot water reduces the energy required to heat the water, improving the overall system efficiency.

13.2 COMPRESSION-CYCLE OPERATING PRINCIPLES

The transfer of heat in the compression-refrigeration cycle is performed by a refrigerant operating in a closed system. Most machines that cool or refrigerate something use the same mechanical refrigeration cycle. This cycle depends upon a few basic physical principles. Some of these principles are intuitive, such as that heat travels from hot to cold. Other principles are less intuitive, such as understanding that boiling is a cooling process. Understanding the following handful of basic physical principles involved makes understanding the mechanical refrigeration cycle much easier.

- “Cold” is not a substance or an energy form; it is the lack of heat.
- Heat travels from hot to cold.
- Liquids absorb large amounts of heat when they boil off to a gas.
- Gases give off large amounts of heat when they condense to a liquid.
- When something is boiling or condensing, its temperature remains the same.
- The temperature at which a liquid boils is controlled by its pressure.

Refrigeration machines do not pump cold in; they pump heat out. Imagine that your air conditioner is like a pump on the bottom of a ship. The purpose of the pump is to pump water out, preferably faster than it leaks in. An air conditioner has a similar purpose, to pump heat out faster than it leaks into your house. The problem is that heat only wants to travel from hot to cold, and when you need your air conditioner it is usually hotter outside than inside. So the challenge is to pump heat from inside, where it is relatively cool, to outside, where it is relatively hot.

Remember that boiling is a cooling process! When a liquid boils, it absorbs large amounts of heat in much the same way that a sponge absorbs water. When you place a dry sponge on a puddle, the sponge turns soggy. The puddle ends up drier, but the sponge ends up wetter. A boiling

liquid acts like a sponge soaking up heat. As the liquid boils it takes heat away from whatever it is touching, leaving the surrounding area cooler. When water is poured on a hot frying pan, clouds of steam billow forth. The energy comes from the frying pan to produce the steam, cooling off the frying pan. The reason people think of boiling as hot is because water boils at 212°F under normal atmospheric pressure, and that is hot. But suppose water boiled at 50°F instead? People might pour boiling water over themselves in the summer to help cool off. It actually is possible to boil water at 50°F! Remember that a liquid’s boiling temperature is controlled by its pressure. Water will boil at 50°F if placed under a low enough vacuum (Figure 13-4).

Refrigerant, like water, can boil at almost any temperature by controlling its pressure. The refrigerant in an air conditioner boils in the cooling coil at a low pressure. The low pressure keeps the refrigerant boiling temperature below the temperature of the air being cooled. The refrigerant temperature stays low even as it absorbs heat because the temperature of a boiling liquid remains stable. This is how heat is absorbed from the space being cooled, by boiling the refrigerant at a low pressure and temperature. During this process, the refrigerant changes from a liquid to a gas. This is done in a component called an evaporator because the refrigerant is evaporating. Heat flows from the warm air traveling over the evaporator to the cold refrigerant boiling inside the evaporator, as shown in Figure 13-5.

The compressor pumps gas from the low-pressure evaporator to the high-pressure condenser (Figure 13-6). The word *compress* means to squeeze. It increases the gas pressure by squeezing the gas into a smaller space. It is important to note that the compressor is designed to pump only gas. Liquid does not squeeze very well. Putting liquid through the compressor will damage it.

When the gas is squeezed into a smaller space, both the pressure and temperature rise. The high pressure raises the refrigerant temperature above the hot outdoor air temperature. Now the refrigerant is sent outside to be condensed at a high temperature and pressure. The heat that was absorbed in the evaporator is expelled outside by condensing the refrigerant back to a liquid. The temperature of the refrigerant stays high even as the refrigerant loses heat because temperature remains constant during condensation. Heat travels from the hot refrigerant to the outdoor

Figure 13-4 Water boils at 50°F under a vacuum.

Figure 13-5 The evaporator is cold because refrigerant boils inside the evaporator.

Figure 13-7 The condenser expels heat from the refrigerant by condensing it from a gas to a liquid.

Figure 13-6 The compressor draws in refrigerant vapor at a low pressure and compresses it to increase the refrigerant pressure and temperature.

Figure 13-8 The metering device drops the pressure and temperature of the refrigerant by restricting the refrigerant flow.

air because the air is cooler than the refrigerant. During this process, the refrigerant changes from a gas to a liquid. This is done in a component called a condenser because the refrigerant is condensing (Figure 13-7). Notice that in both the evaporator and condenser, heat is going from hot to cold. The trick is keeping the refrigerant pressures low in the evaporator where heat is absorbed and high in the condenser where heat is expelled.

The high pressure and temperature of the refrigerant must be reduced before sending it into the evaporator to boil at a low pressure and temperature. The metering device does this (Figure 13-8). The metering device is basically a small restriction that limits the amount of refrigerant entering the evaporator. Limiting the flow of refrigerant increases the pressure before the metering device and decreases the pressure after the metering device. The drop in pressure causes the refrigerant to also drop in temperature. This cold refrigerant is now ready to absorb heat in the evaporator.

13.3 SYSTEM HIGH SIDE AND LOW SIDE

For all practical purposes there are two pressures in the system: the low-side pressure and the high-side pressure. The compressor and the metering device work in partnership to maintain this pressure difference. Figure 13-9 shows how the compressor and metering device, the expansion valve, divide the system into the high- and low-pressure sides.

The low side contains the low-pressure liquid and vapor refrigerant and is the side that absorbs heat. The metering device controls the flow into the evaporator; the expansion of the refrigerant causes a pressure drop. The low side of the system starts at the metering device and extends through the evaporator and the suction line up to the compressor inlet.

The high side contains the high-pressure vapor and liquid refrigerant and is the part of the system that rejects

Figure 13-9 The compressor and metering device divide the system into a high-pressure side and a low-pressure side.

heat. The compressor pumps the refrigerant into the condenser and maintains the high pressure. The high side of the system starts at the compressor outlet and continues through the discharge line, condenser, liquid line, and up to the metering device.

TECH TIP

The body is cooled by evaporation of the perspiration on the skin. The evaporation is reduced when the air is at a higher relative humidity, so the body's cooling mechanism does not work as well. That is why you feel more comfortable at 80° with 40 percent relative humidity as compared to 75° and 90 percent relative humidity. To be effective, air-conditioning systems must remove both heat and humidity.

13.4 REFRIGERATION SYSTEM RELATIONSHIPS

There are key relationships within the refrigeration cycle. Understanding these will improve your understanding of the refrigeration system. The most obvious is the link between pressure and temperature. If the refrigerant is a high pressure, it is also a high temperature. If it is a low pressure, it is also a low temperature. Another important link is between the refrigerant state and its heat content. Gas always has

a relatively high heat content, and liquid always has a relatively low heat content. The heat content of the refrigerant is affected much more by the state of the refrigerant than by its temperature. This is why the refrigerant can have a low temperature and a high heat content leaving the evaporator. Refrigerant will be found in the system in one of three conditions: superheated, saturated, or subcooled. It will be superheated anywhere it is all gas, subcooled anywhere it is all liquid, and saturated anywhere it is changing from one to the other. The refrigerant is superheated leaving the evaporator, through the compressor, and up to the condenser. It is sub-cooled leaving the condenser up to the expansion device. It is saturated in both the condenser, where it is changing from gas to liquid, and in the evaporator, where it is changing from liquid back to gas.

Each of the four main components has an opposite. The compressor and expansion device are opposites. The compressor changes a low-pressure and temperature gas into a high-pressure and temperature gas by reducing its volume. The expansion device changes a high-pressure and temperature liquid into a low-pressure and temperature liquid by expanding its volume. Together they maintain the pressure difference in the system. The condenser and evaporator are opposites. The condenser changes a high-pressure and temperature gas into a high-pressure and temperature liquid, losing a large amount of heat in the process. The evaporator turns a low-pressure and temperature liquid into a low-pressure and temperature gas, gaining a lot of heat in the process.

13.5 HEAT FLOW IN THE REFRIGERATION CYCLE

Heat is added to the refrigerant in the evaporator. Heat from the product load is transferred to the refrigerant as it boils in the evaporator. This is the majority of heat absorbed by the refrigerant. A small heat gain occurs in the piping from the evaporator up to where the refrigerant enters the compressor. Heat gain in the suction line is not desirable and can be reduced by insulating the suction line. The compressor adds a sizable quantity of heat to the refrigerant. This heat is equivalent to the work done in compressing the refrigerant. In a suction gas cooled semi-hermetic or hermetic motor compressor unit, the motor heat is also transferred to the refrigerant.

The heat added in the evaporator and by the compressor is removed in the condenser. The heat is transferred from the refrigerant in the condenser to the air or water flowing over the condenser. The heat balance of the overall system is shown in the following formula: Heat added in the evaporator + heat of compression = heat rejected in the condenser.

13.6 ABSORPTION REFRIGERATION SYSTEMS

Absorption refrigeration systems use heat and the process of absorption instead of a compressor to move the refrigerant. The absorption process takes advantage of the fact that some chemicals have an affinity for other chemicals. One of the most common combinations is to use ammonia as the refrigerant and water as the absorbent. This combination is used in smaller absorption systems. Large absorption chillers use water as the refrigerant and lithium bromide as the absorbent. Absorption systems really have two cycles:

a refrigerant cycle and an absorbent cycle. Some systems use a third gas, typically hydrogen, to help the refrigerant move from the low side of the system back to the high side without using any mechanical devices. Other systems use a solution pump to move solution from the low side to the high side. This discussion will focus on ammonia-water absorption systems used for residential chillers. Figure 13-10 shows a simplified drawing of an ammonia-water absorption cycle.

SAFETY TIP

Ammonia is a poisonous and somewhat flammable gas! Do not attempt to service an ammonia system unless you have received specific training in the safe handling of ammonia refrigerant.

The transfer of heat is essentially the same in the absorption system as in the traditional mechanical compression cycle. Heat is absorbed in the evaporator and rejected in the condenser. Under a high pressure, the ammonia refrigerant condenses from a gas to a liquid in the condenser, giving up its latent heat in the process. The high-pressure liquid now passes through a refrigerant restrictor, where its pressure and temperature are reduced. This low-pressure liquid boils inside the evaporator to a gas, absorbing latent heat in the process and cooling off the water passing over the evaporator coil. So far, the compression and absorption systems are identical. The difference is in how the low and high pressures are created.

In a compression system, the compressor provides the force to create both the high- and low-side pressures. In an

Figure 13-10 Simplified ammonia-water absorption cycle. The solution cycle is on the left; the refrigeration cycle is on the right.

absorption system, the compressor is replaced by three components: the generator, the absorber, and the solution pump.

One component that absorption systems have that is not found on compression systems is the absorber. A second fluid that has an affinity for the refrigerant absorbs the refrigerant in the absorber. This has the effect of “sucking” the refrigerant out of the evaporator and creating a low refrigerant pressure in the evaporator. The absorption process replaces the suction stroke of the compressor. When the vapor refrigerant is absorbed into the solution, it condenses back into a liquid. This gives off a great deal of heat, normally called the heat of absorption. If the heat of absorption is not removed from the solution, the absorption process will stop. Some units actually have two absorbers: a solution-cooled absorber and an air-cooled absorber.

The solution-cooled absorber is where the refrigerant and weak solution are first mixed. The solution-cooled absorber cannot cool the solution adequately enough to remove all the heat of absorption; therefore, much of the refrigerant remains in a vapor state inside the solution. To remove the heat of absorption, the solution passes through the air-cooled absorber, where the heat of absorption is removed and the refrigerant vapor is condensed. A solution pump is used to pump the solution from the low-pressure absorber to the high-pressure generator.

The solution pump is the closest thing to a compressor in concept. The solution pump used in many units is a diaphragm pump and pumps somewhat like a heart, in pulses of pressure that are directed by check valves. On the suction stroke, the valve to the absorber opens, the valve to the generator closes, and solution is drawn into the pump from the air-cooled absorber. On the pressure stroke, the valve to the generator opens, the valve to the absorber closes, and the solution is forced into the generator. The pulsing action of the solution pump causes the solution level in the solution-cooled absorber to rise and fall. This helps entrain refrigerant vapor in the weak solution before it is circulated through the air-cooled absorber. The solution pump and the restrictors are the dividing points between high and low pressures on the system. Of course, the absorbing solution can only absorb a limited amount of refrigerant. In the case of water and ammonia, water will absorb about half its weight in ammonia. At this point, the water-ammonia solution needs to be regenerated for the system to keep operating. The generator does this.

The generator separates the refrigerant and the absorbent by boiling the refrigerant out of the absorbent. This creates a high pressure on the high side of the system. The refrigerant vapor is sent on its way toward the condenser and the weak solution is sent through a restrictor, back to the solution-cooled absorber. The solution cycle is now complete. In addition to the components mentioned, there are a number of other components added to the system for increased efficiency.

SERVICE TIP

Never use standard brass gauges to service an ammonia system! Ammonia attacks the brass. Ammonia systems require gauges made specifically for ammonia.

13.7 EVAPORATIVE COOLING SYSTEMS

Evaporative cooling reduces the air temperature by evaporating water. The heat required to evaporate the water comes from the air, reducing the temperature of the air. Air that has been cooled through direct evaporative cooling still has the same amount of heat, but its temperature is lower and its humidity is higher. This method works well in dry climates, such as in the southwestern United States. Evaporative coolers can drop the air temperature by as much as 20°F if the entering air is dry. Evaporative cooling efficiency increases as the air temperature increases because the water evaporates more readily. Evaporative cooling does not work as well in humid climates, such as coastal areas or the southeastern United States. The high humidity in these areas reduces the effectiveness of evaporative cooling because the water evaporates slowly. The installation and operation costs for an evaporative cooler are much lower than conventional air conditioning using a refrigeration cycle. This makes evaporative cooling popular in large factories and plants, where traditional refrigerated air conditioning would be prohibitively expensive.

Outdoor misters are an increasingly popular form of direct evaporative cooling. Nozzles that spray out microdroplets of water cool the outside air through evaporation. Amusement parks now often use outdoor misters to provide outdoor cool spaces during the summer. Mist systems can also be applied to residential outdoor spaces such as patios (Figure 13-11).

A typical evaporative cooled air conditioner, also called a “swamp cooler,” is shown in Figure 13-12. The unit consists of a water sump, a pump, wetted media to increase the surface area for evaporating water, and a blower to move air. The pump pumps the water in the sump at the bottom to the top of the media where it runs down the media. A float controls the water level in the sump by allowing makeup water to fill the sump when the water level drops. The blower moves outside air across the media and into the house. Water evaporates from the wetted media, reducing the temperature of the air. For this system to op-

erate correctly, air in the house must be allowed to escape. This is normally done by opening the windows. Evaporative coolers are constantly replacing the air in the house with air from outside that has been cooled by evaporation. This type of evaporative cooling is called direct evaporative cooling because the water is directly exposed to the air entering the building.

Indirect evaporative cooling uses a heat exchanger and two airstreams. The heat exchanger keeps the airstreams separate while allowing one airstream to cool the other. Figure 13-13 shows an indirect evaporative cooler. The water evaporation takes place in the airstream that passes through the heat exchanger without entering the building. The airstream entering the building is cooled by the heat exchanger without adding any water to it. Indirect evaporative cooling can be used to precool air before it passes through a traditional compression-cycle conditioning system. This saves energy by reducing the amount of cooling that the compression system must provide (Figure 13-14).

The effectiveness of evaporative cooling can be increased using multiple stages. One manufacturer, Coolerado, makes a twenty-stage indirect evaporative

Figure 13-13 Indirect evaporative cooling process.

cooler using the Maisotsenko Cycle (Figure 13-15). The system uses a unique heat and mass exchanger (HMX) (Figure 13-16) that consists of several plates of a special plastic that is designed to wick water evenly on one side and transfer heat through the other side. The plates are stacked on each other, separated by channel guides. The channel guides divide the incoming air stream into product air and working air. The product air will be delivered into the house; the working air will be expelled to the outside. Product air is always separate from the working air so that the air entering the house does not pick up moisture. Air that is cooled by the first set of plates is used to cool the next set of plates. This process occurs multiple times in a short physical space within the exchanger, resulting in progressively colder product and working air temperatures.

13.8 THERMOELECTRIC REFRIGERATION

A thermocouple is a device composed of two dissimilar metal wires joined on both ends but separated or insulated from each other in between. Thomas Seebeck discovered that small amounts of electrical current flow through the wires if the two junction points are at different temperatures (Figure 13-17). This effect has been

Figure 13-17 Temperature difference between the two junctions creates a DC current flow.

Figure 13-18 A DC current imposed across the two junctions creates a temperature difference.

used for years as a flame safety device in gas-burning appliances. While studying the Seebeck effect in 1834, Jean Pelletier discovered that if a current is imposed on the thermocouple, one end will heat up and the other will cool off. Reversing the direction of the current will swap the hot and cold junctions. This is called the Pelletier effect (Figure 13-18). This characteristic is exploited in thermoelectric refrigeration.

Today's thermoelectric modules typically use semiconductors rather than metal. Figure 13-19 shows the construction of a typical thermoelectric module. These modules can be sandwiched between two heat sinks to produce a unit capable of moving heat. Figure 13-20 shows a complete thermoelectric cooling module, including the heat sinks. Thermoelectric refrigeration is not very energy efficient and is best suited for small loads. Thermoelectric cooling does provide a small, lightweight cooling system for areas that would be difficult to cool with a traditional refrigeration system. Thermoelectric cooling has been applied to electronic systems, space-ships, and picnic coolers.

Figure 13-19 Modern thermoelectric modules use semiconductors to create the Pelletier effect.

Figure 13-20 Complete thermoelectric cooling module, including heat sinks.

UNIT 13—SUMMARY

The purpose of a refrigeration system is to move heat from where it is not wanted to where it is unobjectionable. There are several kinds of cooling systems, including absorption, evaporative, thermoelectric, and mechanical compression. The mechanical-compression refrigeration cycle is the most common. The four main components of the mechanical-compression refrigeration cycle are the compressor, the condenser, the metering device, and the evaporator. The refrigeration cycle is made possible by maintaining a pressure difference between the low side, which absorbs heat when the refrigerant boils in the evaporator, and the high side, which rejects heat when the refrigerant condenses in the condenser. This pressure difference is maintained by the compressor and metering device. The compressor increases the refrigerant pressure by squeezing it; the metering device

reduces the refrigerant pressure by restricting its flow into the evaporator.

Other cooling mechanisms include evaporative coolers, which cool the air by evaporating water; the absorption cycle, which uses heat and an absorbent fluid to create the needed system pressure difference; and thermoelectric cooling, which transfers heat using electric current and the Pelletier effect.

UNIT 14

The Refrigeration Cycle

OBJECTIVES

After completing this unit, you will be able to:

1. explain the fundamental principles behind the refrigeration cycle.
2. identify the four major components of the compression cycle.
3. name the three main refrigeration-system interconnecting lines.
4. identify where in the refrigeration system the refrigerant is saturated, superheated, or subcooled.
5. draw a basic compression-refrigeration cycle and identify the pressure, temperature, state, and heat content in and out of each component.

14.1 INTRODUCTION

The mechanical vapor-compression-refrigeration cycle is used in many types of HVACR systems. It can be found in all sizes of systems, from small dormitory refrigerators to large industrial chillers. The compression cycle has been used for a diverse range of applications, including air conditioning, commercial refrigeration, and industrial process refrigeration. A thorough understanding of the refrigeration cycle is absolutely essential to working in the HVACR field. Understanding exactly what is supposed to take place at any point in the cycle is necessary for proper system installation, servicing, and troubleshooting. Because we only discuss the mechanical vapor-compression-refrigeration cycle throughout this unit, we refer to it as simply the refrigeration cycle for the rest of the unit.

14.2 REFRIGERATION CYCLE FUNDAMENTALS

The refrigeration cycle is a practical application of the gas laws discussed in Unit 11. The system consists of four components: the compressor, condenser, expansion device, and evaporator. All four are visible in the air conditioner shown in Figure 14-1. The names tell what the components do. The compressor compresses, or squeezes, the gas into a smaller volume (Figure 14-2). This raises the gas pressure and temperature. The high-pressure, high-temperature, superheated gas travels to the condenser. This is where the heat is rejected from the refrigeration system. The condenser condenses the refrigerant from a high-pressure, high-temperature, superheated gas to a high-pressure, warm, subcooled liquid (Figure 14-3). The high-pressure, warm, subcooled liquid travels to the expansion device, also called the metering device. The expansion device drops the pressure and temperature of the refrigerant by restricting its flow (Figure 14-4). At the same time, the refrigerant is passing into a larger space and expanding. The combination of pressure drop and expansion dramatically drops

Figure 14-1 The four refrigeration-cycle components can be seen in this packaged air-conditioning unit.

the temperature of the refrigerant and it starts to flash off to a vapor. The refrigerant leaving the expansion device is a low-pressure, low-temperature, low-heat saturated mixture. This low-temperature saturated mixture enters the evaporator, where it evaporates from a liquid to a gas, absorbing heat. The evaporator is the component that cools by absorbing heat from its surroundings (Figure 14-5). The temperature of the refrigerant stays the same through most of the evaporator because the temperature of a boiling liquid is set by its pressure, not by the amount of heat in it.

Figure 14-2 The compressor raises the gas pressure and temperature by squeezing the gas to a smaller volume.

Figure 14-3 The condenser removes heat by condensing gas to a liquid at a high pressure.

After all the liquid has evaporated, the gas temperature increases. The refrigerant leaves the evaporator as a low-pressure, low-temperature, superheated vapor and returns to the compressor.

Figure 14-4 The expansion device drops the refrigerant pressure and temperature by restricting its flow.

Figure 14-5 The evaporator cools by evaporating refrigerant at a low pressure and temperature.

TECH TIP

The refrigerant temperature actually drops slightly as the refrigerant travels through the evaporator. The small pressure drop through the evaporator causes a small but measurable temperature drop from the beginning of the evaporator to the end of the portion that contains saturated refrigerant. Once all the liquid has boiled off, the temperature starts to rise. Normally this occurs in the last 10 percent of the evaporator.

14.3 REFRIGERANT CHANGES THROUGH THE CYCLE

We examine the specific changes in the refrigerant through a typical air-conditioning system. Our example system is a residential air-conditioning system using HFC 410a refrigerant. The refrigeration cycle is a never-ending circle; there is really not a starting or stopping point. This discussion starts with the compressor and works through the cycle. Refer to Figure 14-6 to follow the refrigerant changes through the cycle.

- A. Compressor Suction 118 psig 50°F Superheated Gas** The refrigerant enters the compressor as a low-temperature, low-pressure, superheated vapor. The refrigerant has picked up some superheat in the final evaporator circuit. Superheating is the process of continuing to heat the refrigerant after sufficient latent heat has been added to vaporize all the liquid. Superheating ensures that no liquid slugs will reach the compressor and cause damage to the valves and pistons. The state of the refrigerant is 100 percent vapor.
- B. Compressor Discharge 365 psig 160°F Superheated Gas** The refrigerant leaves the compressor as a high-pressure, high-temperature, superheated vapor. The refrigerant contains both the heat absorbed in the evaporator and the heat of compression from the compressor. The state of the refrigerant is 100 percent vapor.

- C. Beginning of Condenser 365 psig 160°F Superheated Gas** The refrigerant is superheated as it enters the condenser. The first portion of the condenser is used to reduce the temperature of the refrigerant to the saturation temperature. This portion of the condenser is often referred to as the de-superheating section. The state of the refrigerant is 100 percent vapor.
- D. Center of Condenser 365 psig 110°F 50 Percent Liquid/50 Percent Gas Saturated Mix** As additional latent heat is removed, the vapor condenses. The amount of liquid increases and the amount of vapor decreases as the refrigerant travels through the condenser. During this time, the refrigerant temperature remains stable. The state of the refrigerant is 50 percent liquid and 50 percent vapor saturated mix.
- E. End of Condenser 365 psig 100°F Subcooled Liquid** At the lower portion of the condenser, the refrigerant is all liquid. The temperature of the liquid refrigerant is reduced as heat continues to be expelled to the surrounding air. This portion of the condenser is called the subcooling section. Adequate subcooling will prevent the refrigerant from starting to boil as it experiences small pressure drops through the piping or components. Such boiling, called flash gas, can reduce the system capacity. It is desirable to subcool the liquid refrigerant either in the condenser or in the liquid line before the metering device. Subcooling the liquid refrigerant reduces flash gas and increases

mass flow. The state of the refrigerant is 100 percent liquid.

- F. Metering Device Inlet 365 psig 100°F Subcooled Liquid** The refrigerant is a highpressure, warm, subcooled liquid at the inlet of the metering device. The state of the refrigerant is 100 percent liquid.
- G. Metering Device Out 118 psig 40°F 75 Percent Liquid/25 Percent Gas Saturated Mix** The pressure of the liquid refrigerant drops as it goes through the small opening of the metering device, eventually reaching a saturation point at a low pressure and temperature. In passing through the metering device to the low pressure evaporator, some refrigerant is evaporated, cooling the remaining liquid. The refrigerant is typically a mixture of 75 percent liquid and 25 percent vapor at this point.
- H. Evaporator In 118 psig 40°F 75 Percent Liquid/25 Percent Gas Saturated Mix** As the refrigerant enters the evaporator, the air (or liquid, or whatever is being cooled) gives off heat to the refrigerant. The refrigerant takes in this heat as latent heat of vaporization. The refrigerant is about 25 percent vapor and 75 percent liquid at this point.
- I. Evaporator Center 118 psig 40°F 50 Percent Liquid/50 Percent Gas Saturated Mix** Heat from the air or the product being cooled in the evaporator is absorbed by the liquid refrigerant and causes the refrigerant to boil or vaporize. As the compressor draws the vaporized gas from the evaporator, the metering device admits more refrigerant, continuing the process. The refrigerant is about 50 percent vapor and 50 percent liquid at this point.
- J. Nearing the End of Evaporator 118 psig 40°F 25 Percent Liquid/75 Percent Gas Saturated Mix** As the refrigerant continues through the evaporator, the mixture becomes more saturated gas than saturated liquid. However, while there is still liquid in the tube, the temperature remains at the saturation temperature of the refrigerant. The refrigerant is a saturated mixture of liquid and gas.
- K. Leaving the Evaporator 118 psig 50°F 100 Percent Superheated Gas** After all the saturated liquid has boiled to a vapor, the refrigerant vapor starts to increase in temperature in the final evaporator circuit. Superheating is the process of continuing to heat the refrigerant after sufficient latent heat has been added to vaporize all the liquid. Superheating ensures that no liquid slugs will reach the compressor and cause damage to the valves and pistons. The state of the refrigerant is 100 percent gas.

14.4 THE COMPRESSOR

The compressor is a mechanical device for pumping refrigerant vapor from the low-pressure evaporator to the high-pressure condenser. The compressor increases the refrigerant pressure and temperature by decreasing the gas volume. The main types of compressors are reciprocating (piston), rotary, centrifugal, screw, and scroll, shown in Figures 14-7 to 14-11.

Figure 14-7 Piston compressor (reciprocating).

Figure 14-8 Cutaway of a rotary compressor.

The compressor type describes the mechanical operation of the compressor. In the reciprocating compressor, a piston travels back and forth (reciprocates) in a cylinder. Gas is compressed in a reciprocating compressor by squeezing it between the piston and a valve plate at the top of the cylinder. The rotary compressor has a roller that rotates in an orbital motion within a cylinder. Gas is compressed by squeezing it between the roller and

a spring-loaded vane. The centrifugal compressor has a very-high-speed centrifugal impeller that spins within a housing. The gas enters the impeller in the center and is thrown outward by centrifugal force, compressing the gas. The screw compressor uses two rotating screws shaped like augers. Gas is compressed by squeezing it between the two screws. The scroll compressor has a stationary scroll and an orbiting scroll that moves within the stationary scroll. Gas is compressed by squeezing it between the two scrolls.

TECH TIP

Air-conditioning and refrigeration compressors have very large motors. Most of these motors are located inside of the refrigerant system so that the refrigerant can keep the motor cooler. Some large compressors actually have the cold suction vapor come into the compressor at the motor end to provide even greater motor cooling.

14.5 HEAT TRANSFER AND COIL DESIGN

Heat is always trying to reach a state of balance by flowing from a warmer object to a cooler object. Heat only flows in one direction, from warmer to cooler. Temperature difference (TD) is what allows heat to flow from one object to another. The greater the temperature difference, the more rapid the heat flow. For the high side of a refrigeration unit to reject heat, its temperature must be above the ambient, or surrounding, temperature. Also, for the evaporator to absorb heat, its temperature must be below the surrounding ambient temperature (see Figure 14-5).

The two factors that affect the quantity of heat transferred between two objects are the temperature difference and the mass of the two objects. The greater the temperature difference between the refrigerant coil and

Figure 14-12 These two condensing units have the same cooling capacity; the larger unit is a higher-efficiency unit.

the surrounding air, the more rapid the heat transfer. Increasing the coil size and the amount of refrigerant in the coil also increases the rate of heat transfer. Engineers can either design coils to have high temperature differences or larger areas to increase the heat transfer rate.

New high SEER systems are designed with larger coils to increase energy efficiency. Larger coils can operate with a lower temperature difference between the coil and the surrounding air. Less energy is required to produce the lower condensing temperature, improving system efficiency. Manufacturers of new high-efficiency air-conditioning systems use this principle. That is why the newer high SEER outdoor condensing units are significantly larger than older models having the same capacity (Figure 14-12).

The same principle has been applied to the evaporator coils of new high SEER systems. The temperature difference between the evaporator coil and the entering air is less than on older systems. Higher-temperature evaporator coils can pick up the same amount of heat as lower-temperature coils if the coil has greater surface area. The expanded area allows more refrigerant exposure to the airstream for absorbing heat (Figure 14-13).

SERVICE TIP

The larger size of the new high-efficiency equipment may make replacing older equipment more difficult. The increased size of newer equipment may make it impossible to fit it in the same location as an older, smaller, low-efficiency system. Check with the manufacturer for the size of new equipment before starting to change out older equipment.

Air-conditioning and refrigeration design engineers must take into consideration a variety of factors when designing systems for higher efficiency. For example, the higher evaporative coil temperature may produce less dehumidification. In humid climates, dehumidification can be an important part of the total air conditioning. Manufacturers spend thousands of hours and tens of

Figure 14-13 These two evaporators have the same cooling capacity; the larger coil is a new higher-efficiency evaporator coil.

thousands of dollars researching the effective energy efficiency of systems. These tests are carried out in large calibration rooms where the condenser operates at specific temperature and humidity conditions in one area and the evaporator operates under separate conditions in another area.

The results of manufacturing research are incorporated within the manufacturer's technical data sheets provided to the technician during installation. This material may also be found in AHRI's certified equipment guides.

14.6 THE CONDENSER

The condenser is a device for removing heat from the refrigeration system. In the condenser, the vapor at high temperature and high pressure transfers heat through the condenser tubes to the surrounding medium, usually air or water. The first portion of the condenser cools off the superheated gas and lowers its temperature to the saturation point. This part of the condenser is called the de-superheating section. When the temperature of the vapor reaches the saturation temperature, the additional latent heat removed causes condensation of the refrigerant, producing liquid refrigerant. The refrigerant temperature remains the same while it is changing state. The end of the condenser subcools the refrigerant, lowering the refrigerant temperature below the saturation point. This is called the subcooling section of the condenser. There are three types of condensers: air cooled, water cooled, and evaporative (Figure 14-14). The air-cooled condenser uses air as the condensing medium, the water-cooled condenser uses water as the condensing medium, and the evaporative condenser uses both air and water.

Air-Cooled Condensers

Air-cooled condensers consist of three types: natural draft, forced draft, and induced draft. Natural-draft condensers do

not have fans; they rely on natural air currents for air movement across the condenser (Figure 14-15). Forced-draft condensers use a fan to force air across the condenser. In a forced-draft condenser, the cups of the fan blade will be facing toward the coil (Figure 14-16). Induced-draft condensers use a fan to suck air across the condenser. In an induced-draft condenser, the cups of the fan blade will be facing away from the coil (Figure 14-17).

Figure 14-16 The cups of the fan blades face the coil on a forced-draft condenser.

Figure 14-17 The cups of the fan blades face away from the coil on an induced-draft condenser.

SERVICE TIP

Many units with induced-draft condensers require the cabinet panels to be in place for proper airflow. Without the panels in place, air can enter without going across the condenser, reducing the airflow across the condenser.

Water-Cooled Condensers

Water-cooled condensers typically operate at a lower condensing temperature than air-cooled condensers. This produces a lower high-side pressure on water-cooled systems. There are four types of water-cooled condensers: double pipe, open vertical shell and tube, horizontal shell and tube, and shell and coil.

Double-pipe condensers can be a single continuous loop, as shown in Figure 14-18, or several parallel pipes, as shown in Figure 14-19. In either case, the water and refrigerant should flow through the condenser in opposite directions. This is called counterflow (Figure 14-20). This is more efficient because the coldest water contacts the coldest refrigerant and the hottest water contacts the hottest refrigerant. Single-circuit double-pipe condensers can be constructed using a tube in tube, as shown in Figure 14-21, or two tubes soldered together and wrapped in a protective outer tube (Figure 14-22).

Evaporative Condensers

Evaporative condensers use water evaporation to help cool the refrigerant. Evaporation of the water running over

the condenser surface cools the condenser faster than air alone can. Evaporative coolers require makeup water to replace the water that evaporates. Evaporative condensers also require more maintenance than air-cooled systems because the warm open water sump is a perfect place to grow bacteria, mold, and fungus. Also, evaporation causes mineral scale to build up. If the scale is not removed, the condenser's efficiency will drop off.

14.7 THE METERING DEVICE

A metering device controls the flow of refrigerant to the evaporator. It separates the high- and low-pressure sides of the system. High-pressure, high-temperature subcooled liquid enters the metering device and exits as low-pressure, low-temperature saturated mixture. The pressure is low because the compressor is continuously pumping vapor from the evaporator. Two actions occur in the metering device: (1) the pressure of the refrigerant is reduced to a pressure corresponding to the evaporator temperature at the saturated condition, and (2) the refrigerant liquid is cooled to the evaporator temperature by actual evaporation of some of the liquid refrigerant. The saturated mix leaving the metering device is typically 25 percent vapor and 75 percent liquid. There are two general types of metering devices commonly used in modern refrigeration systems: fixed-bore expansion devices and thermostatic expansion valves.

Fixed-Bore Expansion Devices

Fixed-bore expansion devices work by limiting the amount of refrigerant that can pass through the restriction and are best suited for constant heat loads because they cannot adjust to changing load conditions. The pressure difference across a fixed-bore expansion device affects the refrigerant flow through it. A higher pressure difference produces more refrigerant flow; lower pressure differences produce less refrigerant flow. Two types of fixed-bore expansion devices are used: capillary tubes and orifices (Figure 14-23 and Figure 14-24). The capillary tube's length and inside diameter determine the correct amount of liquid flow into the evaporator and the correct pressure drop.

Thermostatic Expansion Valves

A thermostatic expansion valve, TEV, can adjust to varying load conditions and is designed to maintain a constant superheat. The valve measures the suction line temperature with a refrigerant-filled sensing bulb that installs on the suction line leaving the evaporator. The pressure from the sensing bulb is balanced by the evaporator pressure and the adjustment spring pressure. The

Figure 14-23 Capillary tube metering device.

Figure 14-25 The TEV bulb pressure is balanced by the evaporator pressure and spring pressure.

sensing bulb pressure tends to open the valve as the suction line temperature increases; the evaporator pressure tends to close the valve as the evaporator pressure increases (Figure 14-25).

TEVs are used on systems with varying loads because of their ability to adjust to varying load conditions. They are also used frequently on high-SEER systems because of their ability to allow a fully active evaporator under all load conditions (Figure 14-26).

14.8 THE EVAPORATOR

The evaporator is a device for absorbing heat into the refrigeration system. In the evaporator, the saturated refrigerant absorbs heat from its surroundings and boils into a low-pressure vapor. Refrigerant enters the evaporator from the metering device as a saturated mixture. The saturated liquid turns to saturated vapor as the refrigerant travels through the evaporator. The refrigerant is superheated in

Figure 14-26 Thermostatic expansion valve on high-efficiency coil.

the end of the evaporator after all the liquid has boiled off. Some superheat is desirable to ensure that no liquid enters the compressor because liquid refrigerant could damage the compressor.

TECH TIP

Because it takes heat to vaporize water, removing humidity from air also removes heat from the air. The more humidity there is in air, the more heat the air contains. Condensing water on an evaporator coil uses system cooling capacity and reduces the amount of cooling capacity available for changing the air temperature. As the relative humidity of the return air increases, the temperature drop across the evaporator coil decreases.

The evaporator or cooling coil is fabricated from metals such as copper or aluminum or both. These metals are selected because of their good thermal conductivity. Although there are many variations and modifications of evaporators, there are three basic types of construction: bare pipe, finned tube, and plate (Figure 14-27). On finned-tube evaporators, the tubing is interconnected by aluminum fins that serve to both direct the airflow through the coil and increase heat transfer by increasing the surface area of the evaporator (Figure 14-28). Like condensers, evaporators can be forced air or natural draft.

Most evaporators operate below the dew point of the air being cooled. This causes water to condense on them.

Figure 14-27 Different types of evaporators; (a) bare pipe; (b) finned tube; (c) plate.

The condensed water vapor drains into a collection pan and is routed to a drain by tubing (Figure 14-29).

The fin spacing on an evaporator is partly determined by its intended operating temperature. Evaporators that constantly operate below freezing have a wider fin spacing, so frost accumulation does not interfere as much with air flow. Evaporators that typically operate above freezing can use a closer fin spacing because frost does not accumulate. Figure 14-30 shows the difference in fin spacing between a frosting and nonfrosting evaporator coil.

Figure 14-30 The fins are spaced wider apart on coils that operate below freezing.

Figure 14-31 The suction line entering the compressor is the large line; the discharge line leaving the compressor is the small line.

14.9 REFRIGERANT LINES

The components of the refrigeration system are connected by three refrigerant lines: the discharge line, the liquid line, and the suction line. The discharge line is the smaller of the two lines connected to the compressor (Figure 14-31). The discharge line carries the high-pressure, hot, superheated gas from the compressor to the condenser. It is called the discharge line because refrigerant is discharged from the compressor into it. The liquid line carries the high-pressure, warm, subcooled liquid from the condenser to the metering device. The suction line is the larger of the two lines connected to the compressor (Figure 14-31). The suction line carries the low-pressure, cool, superheated vapor from the evaporator coil to the compressor inlet.

Units with all the refrigeration components in one piece of equipment are called packaged units. The discharge, liquid, and suction lines of a packaged unit are contained within the unit. A split system is a unit with parts of the refrigeration system located in different pieces of equipment. Most split-system refrigeration units have the evaporator and metering device located inside and the condenser and compressor located outside. The piece of equipment located outside is called a condensing unit. The two lines connecting these systems are the large suction line and the small liquid line (Figure 14-32). The discharge line is not actually an external line in these systems but part of the outdoor condensing unit. A few split systems locate all the components except the condenser in one piece of equipment and locate the condenser in a separate piece of equipment. These systems also have two lines connecting them together, but they are the lines that go to and from the condenser: the discharge line and the liquid line. On these systems the suction line is an internal line.

Split-system heat pumps have two lines. The large line's function changes depending upon the operating cycle of the

Figure 14-32 Suction and liquid lines on a residential split-system air conditioner.

unit. During cooling, the large line is the suction line and the small line is the liquid line. During heating, the large line is the discharge line and the small line is still the liquid line. To avoid confusion, the large line on split-system heat pumps is often called the gas line because that is what travels through it in either cycle.

14.10 REFRIGERANT STORAGE

The capacity of many refrigeration systems varies depending upon their operating conditions. Capacity changes also produce different refrigerant flows. An increase in refrigeration capacity circulates more refrigerant, while a decrease in capacity circulates less refrigerant. This can make it difficult for systems operating under a broad range of temperature conditions to maintain the desired level of subcooling and superheat. The extra refrigerant needs a place to sit when it is not circulating. Liquid receivers and suction accumulators provide a place for the surplus refrigerant to sit until it is needed. Systems do not usually have both receivers and accumulators. Typically, systems using thermostatic expansion valves use liquid receivers, and systems using fixed bore expansion devices use accumulators.

Liquid Receivers

Liquid receivers are located at the end of the condenser outlet to collect liquid refrigerant (Figure 14-33). The liquid receiver allows the liquid to flow into the receiver and any vapor collected in the receiver to flow back into the condenser to be converted back into a liquid. The line connecting the receiver to the condenser is called the condensate line and must be large enough in diameter to allow liquid to flow into the receiver and vapor to flow back into the condenser. The condensate line must also have a slope

Figure 14-33 Liquid refrigerant drains into the receiver, and vapor flows back to the condenser through the condensate line.

toward the receiver to allow liquid refrigerant to freely flow from the condenser into the receiver. The outlet side of the receiver is located at the bottom, where 100 percent liquid can flow out of the receiver into the liquid line.

Receivers should be sized so that 100 percent of the refrigerant charge can be stored in the receiver. When the receiver is properly sized, it can be used to store the refrigerant during a pump-down cycle or for some types of approved system service.

Some refrigeration-condensing units come with receivers built into the base of the condensing unit (Figure 14-34).

Accumulators

An accumulator is a device located at the end of the evaporator that allows liquid refrigerant to be collected in the bottom of the accumulator and remain there as the vapor refrigerant is returned to the compressor. The inlet side of

the accumulator is connected to the evaporator, where any liquid refrigerant and vapor flow in. The outlet of the accumulator draws vapor through a U-shaped tube or chamber (Figure 14-35). There is a small port at the bottom of the U-shaped tube or chamber that allows liquid refrigerant and oil to be drawn into the suction line. Without this small port, refrigerant oil would collect in the accumulator and not return to the compressor. The small port does allow some liquid refrigerant to enter the suction line. However, it is such a small amount of liquid refrigerant that it boils off rapidly, so there is no danger of liquid refrigerant flowing into the compressor.

Accumulators are often found on heat pumps. During the changeover cycle, liquid refrigerant can flow back out of the outdoor coil. This liquid refrigerant could cause compressor damage if it was not for the accumulator, which blocks its return.

14.11 OTHER REFRIGERATION SYSTEM COMPONENTS

All mechanical refrigeration systems have a compressor, a condenser, a metering device, and an evaporator, but many systems have additional components that help the system perform its job. Other refrigeration system components

that may be found on some refrigeration systems include discharge-line muffler, oil separator, liquid receiver, liquid line filter drier, sight glass, liquid line solenoid, suction to liquid heat exchanger, evaporator pressure regulator, suction line filter, suction accumulator, crankcase pressure regulator, and oil-level control. Some of these components improve the efficiency or reliability of the refrigeration system, while others are essential for specialized systems to operate correctly.

Optional High-Side Components

The discharge-line muffler dampens pulsations and noise created by the compressor. The oil separator removes the oil entrained in the discharge gas and returns it to the compressor crankcase. The liquid line filter drier removes moisture and impurities from the liquid refrigerant and helps protect the system, especially the metering device. A sight glass allows the technician to visually see the condition of the refrigerant in the line. Many sight glasses also have a moisture indicator that changes color when exposed to moisture. A liquid line solenoid is an electrically operated valve used to control the flow of liquid refrigerant. With a normally closed solenoid valve, refrigerant will only flow through when the solenoid is energized. When the solenoid is de-energized, refrigerant does not flow through the solenoid valve. The suction to liquid heat exchanger exchanges heat between the warm liquid line and the cool suction line. This increases both the suction gas superheat and the liquid line subcooling.

Optional Low-Side Components

The evaporator pressure regulator, EPR, controls the pressure in the evaporator. It will not allow the evaporator pressure to drop below the EPR setpoint. EPR valves are used on systems with multiple evaporators operating at different pressures and temperatures. The evaporators share a common suction line but are able to maintain separate evaporator pressures because of the evaporator pressure regulators. Suction line filters are used to protect the compressor from contaminants. Typically, suction line filters are used when replacement compressors are installed. The filter is removed after the system has operated long enough for the filter to do its job. Suction line accumulators are used to ensure that no liquid enters the compressor. They are commonly used on heat pumps. Crankcase pressure regulators, CPR, are valves used to keep the suction pressure to the compressor from rising above the setpoint of the CPR valve. CPR valves are commonly used on commercial freezers. They keep the compressor from being overloaded when the evaporator temperature is above its normal operating temperature. Oil-level controls are used on systems with multiple compressors that are piped into common discharge and suction headers.

UNIT 14—SUMMARY

The mechanical vapor-compression-refrigeration cycle is the most common of all refrigeration cycles. The four main components are the compressor, the condenser, the metering

device, and the evaporator. The refrigeration cycle is made possible by the pressure difference, which is maintained by the compressor and metering device. The compressor increases the refrigerant pressure by squeezing it; the metering device reduces the refrigerant pressure by restricting its flow into the evaporator. The low side absorbs heat when the refrigerant boils in the evaporator; the high side rejects heat when the refrigerant condenses in the condenser. The refrigerant is a superheated gas leaving the evaporator, through the compressor, and going up to the condenser. The refrigerant is saturated in the condenser, where it changes state from a gas to a liquid. The refrigerant is subcooled in the last portion of the condenser. It remains a subcooled liquid, leaving the condenser up to the expansion device. It is saturated, leaving the metering device due to a drop in pressure. The refrigerant is saturated throughout the evaporator until the last 10 percent, where it picks up superheat before returning to the compressor.

UNIT 15

Compressors

OBJECTIVES

After completing this unit, you will be able to:

1. identify the major types of compressors.
2. explain how each type of compressor works.
3. give examples of applications for each type of compressor.
4. explain horsepower and compressor capacity.
5. explain common compressor problems.

15.1 INTRODUCTION

The compressor is a mechanical device for pumping refrigerant vapor from the low-pressure side in the evaporator to the high-pressure side in the condenser. The word *compress* means to squeeze. The compressor reduces the volume of the refrigerant gas by squeezing it. Since gas volume, pressure, and temperature are related, reducing the volume causes an increase in both pressure and temperature.

Compressors are identified by the mechanical parts that perform the actual pumping of the refrigerant vapor. In the reciprocating compressor, a piston travels back and forth in a cylinder (Figure 15-1). The scroll compressor has a stationary scroll and an orbiting scroll that moves within the stationary scroll (Figure 15-2). The centrifugal compressor uses an impeller rotating within a housing at very high speed, as shown in Figure 15-3. The screw compressor uses a rotating screw within a tapered housing (Figure 15-4). The rotary compressor uses an offset rolling piston that orbits within a cylinder (Figure 15-5).

The type of compressor used depends on the application. Application factors include the type of refrigerant, the size (tonnage), the pressure difference, the evaporator and condenser saturation temperatures, and the type of cooling available for the compressor. Figure 15-6 indicates the various applications for the different types of compressors.

15.3 POSITIVE-DISPLACEMENT COMPRESSORS

Compressors are commonly divided into two large groups by their operating principle: positive displacement and non-positive displacement. Positive-displacement compressors move the gas by taking it into a space and then replacing that space with something physical, like a piston. Basically, whatever is in the space is positively shoved out by the mechanism. Blocking the discharge port of a positive-

Figure 15-6 Compressor application by types.

displacement compressor can cause compressor damage, because the gas must go somewhere.

SAFETY TIP

Closing off or blocking the discharge valve on a positive-displacement compressor while it is operating can be dangerous. With no place to go, the discharge pressure increases rapidly, creating extremely high pressures.

15.4 NONPOSITIVE-DISPLACEMENT COMPRESSORS

Nonpositive-displacement compressors do not fill the gas space with something else. These machines operate like giant fans or turbines turning at very high speeds. They basically throw the refrigerant outward, creating an increase in pressure and temperature. This outward force is like the centrifugal force you feel on those spinning pieces of playground equipment, merry-go-rounds. These compressors are called centrifugal compressors after the physical force that makes them work. The discharge of a centrifugal compressor should not be blocked because it can set up a condition known as surging, which can damage the compressor.

15.5 OPEN-DRIVE COMPRESSORS

The oldest compressor design is the open-type compressor shown in Figure 15-7. Open compressors may be driven by means of a pulley on a shaft that extends through a seal. The pulley is driven by a separate motor or engine. Open compressors have performed reliably over the decades but have been largely superseded by newer designs. Open

machines (unlike hermetic) can be used with ammonia (NH₃) refrigerant as long as all components and accessories are made of iron or steel (or other suitable materials). Open compressors range in size from less than a ton capacity to several hundred tons in capacity. They are often used for refrigeration and industrial applications where rugged,

Figure 15-8 Industrial-duty open-type compressor.

serviceable machinery is required. Figure 15-8 shows an industrial-duty open compressor.

All open compressors use a shaft seal to prevent refrigerant from leaking around the crankshaft. These seals are subject to forming leaks and need to be checked during planned maintenance or service.

In direct-drive compressors (Figure 15-9), the motor shaft is coupled to the compressor shaft and driven at motor speed.

Belt-driven machines offer the flexibility of selecting a compressor speed to match the load. The belts require additional space and a protective guard. They require increased maintenance and increased power due to operational losses. An example of a belt-driven compressor is shown in Figure 15-10.

One advantage of an open-drive compressor is that the motor and compressor are separate units so that the motor or compressor can be repaired or replaced without having to buy a complete system. Another advantage is that the motor's heat is not absorbed in the refrigerant, so it does not have to be rejected in the condenser like most other compressor types.

The most common use of open compressors is for automobile air conditioning. In automobiles, the air-conditioning compressor is driven by a pulley and belt off of the main vehicle engine. Open compressors are also used for transport

refrigeration on trucks, tractor trailers, and shipping containers. These applications generally use a separate engine to drive the compressor.

15.6 HERMETIC COMPRESSORS

Hermetic compressors have their mechanical components and electric motor enclosed in a single welded shell (Figure 15-11). The compressor crankshaft extends into the rotor of the electric motor, eliminating the need for drive components. The benefits of hermetic compressors include:

- Reliable operation due to the direct connection between the motor and compressor with no belts or couplings to wear or break
- No shaft seal to leak because the motor and compressor are sealed in a welded steel shell
- Very compact in size, permitting increased refrigerated storage space
- Lower sound level, ideal for domestic appliances

Figure 15-11 Hermetic compressor.

Figure 15-12 A glass-to-metal connection is used to isolate the electrical terminals from the metal compressor shell.

One challenge with hermetic compressor design is to pass electrical connections through the welded steel shell without grounding out to the shell. This is accomplished by passing the electrical connections through glass or ceramic insulators. High-strength glass insulates the terminals from the metal that the terminals pass through (Figure 15-12).

SAFETY TIP

The terminal cover should always be in place when operating a hermetic compressor. Abnormally high current can create enough heat to crack the glass holding the terminals, and the electrical terminals can shoot out under high pressure. This is usually followed by ignition of the refrigerant oil. This acts like a bullet followed by a flamethrower. This is known as terminal venting, a rare but potentially deadly occurrence.

The shells on reciprocating hermetic compressors are called low-side shells because the suction gas enters the shell. The motors in hermetic compressors are cooled by the refrigerant vapor traveling over them. Operating a hermetic compressor on a low charge can cause the motor to overheat because of poor motor cooling. Many hermetic compressor manufacturers do not like their compressors operating in a vacuum. The motor varnishes used in the motor winding lose some of their insulating ability under deep vacuums, and motors can arc out very quickly, even before they have time to overheat. Keeping the refrigerant clean is especially important in a system with a hermetic compressor because the refrigerant and oil flow directly over the motor and all internal electrical connections.

Hermetic compressor units (Figure 15-13) are made in a variety of sizes, from tiny fractional horsepower units meant for small appliances to larger units up to about 20 tons for

Figure 15-13 Hermetically sealed electric motor compressor units. (Courtesy Danfoss Inc.)

air-conditioning use. They are sometimes called welded hermetics, full hermetics, or sealed hermetic compressors.

The welded steel shell prevents any field service access, so there are no service procedures to replace damaged internal components such as motors, bearings, valves, and so on. If damaged or defective, the entire hermetic compressor is replaced. Reciprocating hermetic compressors are usually internally spring isolated to reduce the inherent vibration caused by the reciprocating action of the pistons (Figure 15-14).

Figure 15-14 Cutaway view of hermetic compressor showing internal isolation spring inset.

15.7 SEMIHERMETIC COMPRESSORS

Semihermetic compressors also have the motor and mechanics in one enclosure, but the enclosure has some form of access, like bolted plates and gaskets. The semihermetic motor compressor unit, which is field serviceable by virtue of its bolted construction, has evolved over the past fifty to sixty years. It may have a bolted cast-iron construction or a bolted, flanged, drawn steel shell. An advantage of semihermetic compressors is that they provide the advantages of hermetic compressors but are still field or factory repairable. Parts such as valve reeds, gaskets, bearing inserts, or motor stators may be replaced on various units. These machines are known by a variety of names: semihermetic, serviceable hermetic, accessible hermetic, and bolted hermetic. The units are available in sizes that range from approximately 0.25 to 125 tons cooling capacity. Figure 15-15 shows a semihermetic compressor used for medium and low-temperature refrigeration.

Cooling

Semihermetic compressors can be classified by their means of motor cooling: air cooled or refrigerant cooled. Air-cooled semihermetic compressors use airflow over the motor portion of the compressor to cool the compressor motor. The refrigerant goes straight into the cylinders on these compressors. Maintaining a minimum superheat of 20°F at the compressor is critical for air-cooled semihermetic compressors. Refrigerant-cooled compressors use the refrigerant gas for cooling, much like hermetic compressors. They can operate safely at a much lower superheat because the refrigerant goes over the motor first before entering the cylinders.

Duty

The size and type of motor a compressor needs depends upon the job it is required to do. Hermetic and semihermetic compressors come with a motor already matched to the compressor. For this reason, hermetic and semihermetic

Figure 15-15 Semihermetic compressor used for medium- and low-temperature refrigeration.

compressors are classified by the saturation temperature of the returning suction gas they are designed to handle. Two semihermetic compressors can be identical mechanically but have different motors because they are intended for different applications. In general, semihermetic compressor applications are classified as high temperature, medium temperature, low temperature, and ultra-low temperature.

SERVICE TIP

Although semihermetic compressors are field serviceable, for cost reasons many are removed and sent to companies that specialize in remanufacturing compressors. These facilities are set up to thoroughly clean and inspect the entire compressor and replace those parts that have worn beyond tolerance. Field service work is commonly done for large compressors that would be extremely difficult or expensive to remove.

15.8 RECIPROCATING COMPRESSORS

Reciprocating compressors have been used in refrigeration service for a long time. The reciprocating compressor is used in the majority of domestic, small commercial, and industrial condensing unit applications. Reciprocating compressors are available in open, hermetic, and semihermetic designs.

In a reciprocating compressor the piston is driven up and down in the cylinder by the connecting rod and crankshaft (Figure 15-16). Besides the compressor body, the

Figure 15-16 The crankshaft rotates while the piston moves up and down.

Figure 15-17 Reciprocating compressor parts.

basic mechanical components of a reciprocating compressor are the crankshaft, connecting rods, piston, wrist pin, valves, and valve plate (Figure 15-17).

The crankshaft operates like a rotating lever. Two types of crankshafts are the crankthrow and the eccentric. Crankthrow crankshafts look like the crankshaft on an engine; they have offset sections where the rods attach (Figure 15-18). The ends of the rods bolt around the crankshaft on a crankthrow crankshaft. Eccentric crankshafts look like the cam on an engine. An eccentric crankshaft is a straight shaft with offset lobes (Figure 15-19). The connecting rods used with eccentric crankshafts are one piece; they slide over the crankshaft when the compressor is assembled. An eccentric crankshaft provides smoother operation than a crankthrow crankshaft.

The connecting rods are either two piece for crankthrow crankshafts or one piece for eccentric crankshafts (Figure 15-20). The shaft on some connecting rods has a hole that carries oil up the piston wrist pin. Other systems use oil in the refrigerant vapor inside the compressor to lubricate the piston wrist pin.

Figure 15-18 Crankthrow crankshaft.

Figure 15-19 Eccentric crankshaft.

Figure 15-20 One-piece and two-piece connecting rods.

The pistons are usually manufactured slightly smaller in diameter than the cylinder they will operate in. Piston rings are used on large compressors to fill this gap (Figure 15-21). Small compressors do not have rings but "oil grooves" where oil collects to help block gases from "blowing by" the pistons during the compression stroke.

The valve plate serves as the top of the cylinder and holds the valves. Typically, the discharge valves are located on top of the valve plate and the suction valves are located on the underside of the valve plate. The valves are self-operating: they open and close due to pressure difference. They are sometimes spring loaded, but the principle is the same. Note that this is quite different from an automobile engine, where the valves are mechanically opened and closed by a camshaft synchronized to the crankshaft.

Figure 15-22 shows the different types of reciprocating cylinder valves: (a) the flexing reed valve; (b) the floating

Figure 15-21 Compressor piston with rings.

reed valve; (c) the ring valve; and (d) the reduced-clearance poppet valve used for the discus compressor.

Pistons within the compressors may have the suction valve located in the top of the piston; this is classified as a valve-in-head type, or the piston may have a solid head, with the suction and discharge valves located in a valve plate or cylinder head.

Figure 15-22 Typical reciprocating compressor cylinder valves: (a) flexing reed valve; (b) floating reed valve; (c) ring valves; (d) reduced-clearance poppet valve, discus compressor.

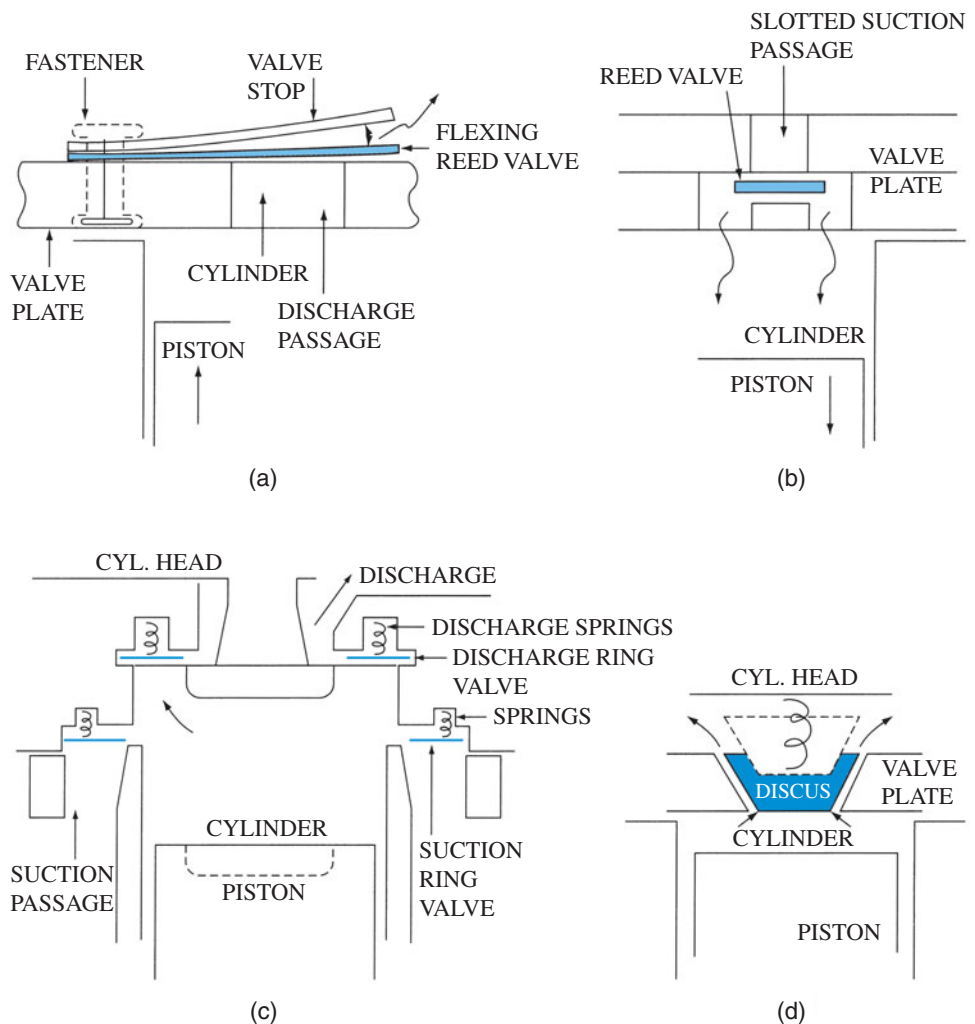

Figure 15-23 shows the complete compression cycle of a reciprocating piston compressor. Position (a) shows the beginning of the intake cycle; the suction valve has not opened because the pressure in the cylinder is still above the system suction pressure. As the piston strokes down in the cylinder, the pressure will drop to a point where it is below the pressure in the suction manifold. At (b), the higher pressure in the suction line forces the suction valve open, and cold (but superheated) low-pressure suction gas from the evaporator will flow into the cylinder. At (c), the piston continues downward, drawing in refrigerant vapor. At (d), the refrigerant pressure above the rising piston forces the suction valve closed and the discharge valve open. At (e), the rising piston pushes the high pressure and temperature refrigerant out the discharge valve. At position (f), the suction valve remains closed and the discharge valve also closes because the system discharge pressure is greater than the pressure left in the cylinder.

15.9 CYLINDER GAS REEXPANSION

The clearance volume is the space between the top of the piston and the cylinder head. During the compression stroke, gas leaves the cylinder and passes into the discharge manifold until the pressure in the cylinder is the same as

INTAKE (SUCTION) CYCLE

DISCHARGE (COMPRESSION) CYCLE

the discharge manifold pressure. At the completion of the compression stroke, this space is filled with compressed gas that is not going anywhere. This gas will have to expand on the downstroke before the pressure can drop to a point to admit fresh suction gas. This reexpansion represents wasted work and lost capacity. The compressor designer strives to minimize the clearance volume while at the same time leaving adequate room for thermal expansion and for unwanted incompressible slugs of oil and liquid refrigerant. These slugs can enter the cylinder, and they possess the ability to do great damage to the valves, piston, and cylinder head. Theoretically, 0 percent clearance volume would be good; practically, it would be disastrous.

Figure 15-24 shows a pressure-volume plot that is used to study reciprocating compressor performance. The horizontal axis represents the cylinder volume, and the vertical axis represents the cylinder pressure. A piston, cylinder, and valves have been added to graphically illustrate the stroke. Figure 15-25 uses this type of graph to show the reexpansion volume at the beginning of the downstroke. Point A represents top dead center of the piston stroke and shows the clearance volume and discharge pressure. As the piston travels down, the trapped compressed clearance volume gas has to reexpand until it reaches suction pressure at point B. Figure 15-26 illustrates the useful portion of the intake stroke. As the downstroke continues from point B to point C, the cylinder pressure is below the suction manifold pressure, and the pressure difference opens

Figure 15-24 The two elements of a pressure-volume plot, used in the study of reciprocating compressor performance.

the suction valve and fills the cylinder with new refrigerant vapor. The suction valve closes at the bottom of the stroke.

Figure 15-27 shows the compression stroke from bottom dead center (C) to point D. This compresses the gas to a point about equal to discharge manifold pressure. During the compression stroke, both suction and discharge valves are closed. The piston has traveled from 100 percent of cylinder volume to a point about 20 percent of cylinder volume. On air-conditioning R-410A applications, the suction pressure would be about 118 psig (40°F saturation) and the discharge pressure about 417 psig (120°F saturation).

Figure 15-27 Compression stroke, C to D, with cylinder valves closed.

Figure 15-28 shows the completion of the compression stroke from point D to A (top dead center). The cylinder pressure exceeds the discharge manifold pressure and forces the gas out. The gas occupying the clearance volume space (approximately 4 percent volume) remains. This trapped gas will remain and must reexpand with the next intake stroke.

The previous illustrations assume an ideal world with no pressure losses across the valves and minimum turbulence. A more realistic view is found in Figure 15-29, which shows pressure losses. The area enclosed by points A, B, C, and D on the pressure-volume plot represents the work done by the compressor on the gas passing through the cylinder.

Figure 15-28 Discharge portion of compression stroke, D to A.

Figure 15-29 Complete P-V diagram for a one-cycle compressor cylinder.

Cylinder gas reexpansion causes inefficiency because part of the intake stroke is not used to bring in new gas. Some other types of positive-displacement compressors (scroll, rotary, and screw) do not have trapped reexpansion gas to deal with and thus have inherently higher efficiencies.

Increasing the discharge pressure and/or reducing the suction pressure reduces the output of the compressor. Increased pressure difference increases the amount of cylinder gas reexpansion because the distance the piston must travel before the suction valve opens increases. Other things being equal, a compressor will produce the greatest output by running at the highest suction temperature and the lowest discharge temperature practical: the most work at the lowest energy rate.

TECH TIP

Discus valves in compressors make a significantly different sound than other valve mechanisms. Occasionally, technicians who are not familiar with the sound may feel that the compressor has a bad component or is about to fail. Discus compressors are identified on the nameplate. Check the nameplate before you jump to the wrong conclusion.

15.10 ROTARY COMPRESSORS

Rotary compressors are widely used in small welded hermetic sizes to power small refrigerated appliances, window air conditioners, packaged terminal air conditioners, and ductless split systems. They are efficient and run smoothly and quietly. Two common designs for rotary compressors

Figure 15-30 Stationary-blade (rolling piston) rotary compressor.

are rotary blade and stationary blade (rolling piston) (Figure 15-30). They are not internally spring isolated, so external vibration isolators must be used on the mounting feet.

Both types of rotary compressors use a high side shell. The refrigerant inside the shell is the discharge gas, not the suction gas. This means that the motor is in a very hot vapor as compared to other compressors. Most other compressors use a low side shell, where their motors are operating in a much lower temperature environment. Rotary compressors are found in window AC units, window heat pumps, and other small units because they are higher efficiency and lighter than reciprocating compressors.

Rolling Piston—Stationary Blade Operation

Rolling piston compressors are also called stationary blade compressors. They use an offset rolling piston that seals against a blade that remains stationary and moves in and out of its slot to seal against the rolling piston. The rolling piston is a rotating off-center cam or lobe that sweeps a path inside a round cylinder (see Figure 15-30). The drive shaft is centered in the cylinder. A close-fitting spring-loaded sliding blade follows the piston and separates the cylinder openings for suction (inlet) gas and discharge (outlet) gas.

As the rolling piston rotates, gas will flow in and fill the suction cavity due to pressure difference, much the same as in a reciprocating compressor (Figure 15-31). The piston continues to rotate, closes off, and passes the suction port and compresses the gas until its pressure is high enough to flow out through the discharge (reed)

Figure 15-31 Compression cycle for a rotary compressor.

valve into the discharge manifold. No suction valve with its inherent pressure loss is needed, so volumetric efficiency is high. Because of the rotating rather than reciprocating piston motion, vibration levels are reduced and are easier to dampen (externally).

Compact hermetic versions are built in sizes from small fractional horsepower up to about 5 hp. Close production tolerances are required for the rolling piston to clear the cylinder but come close enough for the oil film to provide a seal and lubricate between the active surfaces. Rolling-piston rotary compressors are commonly used in window air conditioners, package terminal units, and appliances.

Rotary Blade Operation

Rotary blade compressors are used in refrigeration applications. One type is used in small applications like residential refrigerators and freezers, while another is used primarily in larger commercial refrigeration applications.

A large off-center rotating shaft carries multiple blades in slots, and they have a reciprocating action as they move in and out, following the cylinder walls. The moving cavities (cells) formed between adjacent vanes fill with gas as they sweep by the suction port. The gas trapped in the cell is then compressed as the moving space between the vanes, cylinder wall, and shaft is reduced. Finally, the compressed gas is released through a discharge port and the process repeats. An oil-flooded design provides sealing and lubrication. Large rotary-vane compressors usually are open-type compressors with external drive shafts. Typically, these machines are used as booster compressors for low-temperature ammonia systems as well as for single-stage compressors for industrial and process applications.

Rotary Compressor Operational Characteristics

Rotary compressors are somewhat tolerant of small amounts of liquid. The spring-loaded blade can lift off the rolling piston and let liquid scoot under it if liquid is trapped and cannot escape through the discharge valve. Rotary compressors are also more efficient than reciprocating compressors because they do not have any clearance volume.

Because rotary compressors use a high-side shell, the refrigerant absorbed by the oil in a rotary compressor takes somewhat longer to leave than with low-side-shell hermetic compressors. Systems with a small refrigerant charge will operate as if they are undercharged for several minutes until all the refrigerant leaves the oil.

Rotary compressors are constructed of precisely machined metal parts with no gaskets or rings. Maintaining clean systems and proper lubrication is critical. Long refrigerant lines can cause problems with rotary compressors because they can lose their oil in the lines and seize. Small impurities can also cause them to seize. Even a hair placed between the rolling piston and the cylinder can cause it to seize.

Keeping condensers clean is especially important with rotary compressors because they are cooled by the hot discharge gas. Dirty condensers lead to overheated compressors.

Figure 15-32 A movable scroll orbits inside a fixed scroll.

15.11 SCROLL COMPRESSORS

Scroll compressors compress gas between two close fitted spiral scroll members (Figure 15-32). One is fixed and the other moves (but does not rotate) in an orbital path. The only rotating part in a scroll compressor is the motor shaft. Progressively reducing cavities compresses the refrigerant gas with little or no vibration.

Scroll compressors are positive-displacement machines with high volumetric efficiencies, currently available in sizes from about 1 hp to 30 hp. Because they are approximately 10 percent more efficient than a comparable reciprocating compressor, they have experienced extraordinary growth in the world markets of residential and commercial air conditioning and refrigeration. Scroll compressors are built in a welded hermetic design.

Scroll Compressor Operation

The sides of the scroll shape are called flanks; the edge of the scroll is called the scroll tip. For a scroll machine to work well, it must be finished to very close tolerances so the contact between the flanks and tips of the scroll members are very snug. Suction vapor is captured in pockets at the outside of the scroll members. The pockets close as the scroll orbits, trapping a small quantity of refrigerant vapor in each pocket. The trapped pocket of vapor is forced around the scroll toward the center in an ever-decreasing pocket size as the scroll continues to orbit. The refrigerant's pressure and temperature increase as the pocket size decreases. The compressed gas is discharged at the center through an opening in the fixed scroll.

Figure 15-33 shows the key components of a scroll compressor. Notice that the suction gas enters at the side because of the low-side shell design. The discharge gas exits near the top.

Scrolls are classed as compliant or noncompliant designs depending on the method used to accomplish the critical task of gas sealing. Compliant designs can provide radial compliance by the use of an Oldham coupling, which allows some side-to-side slipping between the shaft and the moveable scroll. The movable scroll is held against the fixed scroll through centrifugal force. This

Figure 15-33 Scroll compressor parts shown in a cutaway.

allows the scroll flanks to maintain close contact, and yet the orbiting scroll can separate and unload to pass a small slug of liquid. Axial compliance is maintained by an adjustable force applied to maintain the seal between the scroll tips during compressor operation. This force is provided by the discharge gas and is released on shut-down. A compliant scroll compressor can handle small amounts of liquid refrigerant without damage. However, large amounts of liquid will create enough pressure on the flanks of the scroll to snap them off.

Figure 15-34 shows a cross section of a scroll compressor. The Oldham coupling is used to drive the orbiting scroll providing radial compliance, permitting the compressor to handle liquid slugs.

Figure 15-35 shows the scroll compression sequence in diagram form. One pair of cavities is shown in the compression sequence.

Scroll compressors have very few moving parts as compared to reciprocating compressors. Scroll compressor motors are pressed to fit into the compressor housing. The compressor is not spring isolated inside the welded

Figure 15-34 Partial cutaway of a scroll compressor. (Courtesy Danfoss Inc.)

shell. Vibration isolation is only external. As a result, scroll compressors can sometimes produce an unusual high-pitched sound. Some manufacturers enclose these compressors in soundproofing boxes to keep the sound level (db) low enough to meet standards.

Figure 15-35 Scroll compressor movement; notice that the red dots on the scrolls stay very close together through the compression cycle.

TECH TIP

Scroll compressors may be noisy on startup and shut-down, making a very loud rattle. This rattle is caused by the movable scroll rattling until the discharge pressure is high enough to seal the scroll tips and the compressor speed is high enough to hold the moveable scroll tightly against the fixed scroll. It does not indicate a problem in the compressor.

Scroll Compressor Precautions

Most scrolls are low-side shells. The majority of the shell is low side, but the top of the scroll is where the high-side gas leaves. Do not allow the suction pressure to drop below 25 psig during charging or below 7 psig for even a few seconds. Low pressures can overheat the scrolls and damage the compressor. Do not run a unit with a scroll compressor with the suction valve closed. The compressor can pull into a vacuum and cause internal electrical terminal arcing, instantly killing the compressor.

Unlike most reciprocating compressors, scroll compressors are directional. They only work in one direction. Scroll compressors are extremely noisy when running backward. They also will not compress when operated backward. Check for proper rotation when starting systems with three-phase scroll compressors. This can be done with gauge manifolds. If normal suction and discharge pressures are seen soon after startup, the rotation is correct. If normal suction and discharge pressures do not quickly develop, shut off the machine and reverse any two-compressor power leads. Then recheck.

Early scrolls often experienced refrigerant backflow every time they shut down. The high-pressure discharge gas would push through the compressor to the suction side and make the compressor spin backward. Momentary power interruptions would occasionally cause the compressor to operate backward because of this. Today, systems using scroll compressors typically use anti-short cycle controls to avoid immediate restarts. On today's scroll compressors, a discharge line check valve prevents continued backflow through the scroll when shutting down. A momentary sound will be heard for one or two seconds as the internal pressures equalize backward through the scroll.

It is possible for a scroll to seal some refrigerant in it when it shuts down. Always be sure to vent both the high and the low sides before working on the lines, especially if brazing.

15.12 TWO-STEP SCROLL COMPRESSORS

The Copeland two-step scroll compressor operates much like the standard scroll. The difference is that by activating an internal solenoid, the compressor's capacity can be changed from 67 percent to 100 percent instantly. For example, a 36,000 BTUH compressor (BTUH is the commonly used unit referring to BTU/hr in the industry) would provide approximately 24,000 BTUH on the low step of cooling.

A rotating internal plate opens and closes two drilled ports in the scroll (Figure 15-36). When these two ports are open, refrigerant exits the scroll in the first compression chamber. This balances the pressure at this point in the compression cycle. By moving the actual starting point of the compression cycle a little closer to the center discharge, the compressor is partially unloaded. The stepping between full and partial load capacity is done while the compressor is running.

The term *partially unloaded* means that the compressor capacity has been reduced from its full load capacity. Large commercial refrigeration compressors have used unloading techniques for many years to save energy. This two-step scroll was designed for that same energy-saving purpose. The unloading allows the compressor to run longer when the residence is under a lighter load, such as summer nights and early mornings or warm spring or fall days. Longer run times can increase the dehumidification part of the air-conditioning process.

The two-step scroll compressor can be used in heat pumps. Typically, most homes require more heating capacity than cooling capacity. Using a system with too much capacity in cooling produces inefficient operation and poor dehumidification. The two-step scroll allows a heat pump to have a high capacity in heating and a lower capacity in cooling, improving the efficiency in both heating and cooling.

Two-Step Scroll Compressors Operation

The second step of cooling is controlled by an electronic module (Figure 15-37). This control module receives a 24 V AC signal from the thermostat's second stage. Within the module, the 24 V AC is rectified to DC, which operates the internal unloading solenoid coil. The module has an

Figure 15-36 The two-step scroll compressor activates a solenoid to go from 67 to 100 percent capacity.

Figure 15-37 Control module for two-step scroll compressor.

operating input voltage of 18–28 V AC at 20 V AC. The internal coil has an operating input voltage range of 12–27 V DC.

CAUTION

The unloading solenoid coil operates on 24 V DC and will be damaged if connected to 24 V AC. If the internal coil is damaged, the compressor will only operate on the first step of cooling.

15.13 DIGITAL SCROLL COMPRESSORS

Digital scroll compressors get their name from the fact that they only operate under two conditions: either at 100 percent capacity or 0 percent capacity. It is the ability to switch very quickly between full-on capacity to full-off capacity that allows digital scrolls to produce an infinite range of capacity. The compressor motor operates at a constant speed. The scroll's capacity is controlled by an external solenoid. This solenoid can be energized and de-energized at a rate fast enough to change the effective compressor capacity from 10 to 100 percent as needed.

When the scroll is unloaded, the current draw is reduced. This allows the compressor to provide exactly what is needed for the application and to provide outstanding energy savings.

The 10 percent minimum capacity is designed to ensure that the compressor gets proper lubrication. If the solenoid were energized all of the time, the compressor would have no refrigerant flowing, and it would not have any lubrication. Under these conditions, the compressor would quickly destroy itself.

The digital scroll compressor works much like turning a light off and on very quickly. If you are fast enough with the switch, you could make the light range from a slight glow to 100 percent bright. That is how fast the solenoid turns the scroll off and on.

Digital Scroll Compressors Operation

The external solenoid valve controls the downward refrigerant pressure on the top scroll. When this solenoid is energized, the pressure on top of the scroll is released into the suction line (Figure 15-38). With the pressure reduced on the top scroll plate, it is allowed to lift ever so slightly from the orbiting lower scroll plate. This allows gas to scoot under the scroll, effectively stopping compression. It is like sticking a pin in a balloon: it takes less than a blink of an eye for the pressure to be released. Once the solenoid is de-energized, the compressor instantly begins to compress refrigerant again.

A digital compressor controller turns the solenoid on and off. The controller is connected to a thermostat that

tells it how much cooling is needed. In addition, there are a number of safety devices and sensors that can be attached to this controller.

One major safety/control device that can be added to a digital scroll compressor is the optional refrigerant-injection system. As discussed later in this unit, overheating of all compressors occurs as they are used for lower and lower evaporator temperatures. The refrigerant-injection system on the digital scroll and the scroll's ability to change its effective compression ratio through unloading has allowed it to be successfully used in low-temperature applications. The discharge temperature thermistor and optional suction transducer work through the compressor controller to keep the internal operating temperature below the critical temperature.

Digital Scroll Applications

Digital scroll compressors are being used for refrigeration and heat pump applications under operating conditions that would be detrimental to most compressors. The controller, along with its safety and control sensors, helps to keep the compressor within its operating limits.

Digital scroll compressors are available in sizes ranging up to over 10 tons. The large compressors have been used economically in heat pump applications with outdoor temperatures below 0°F. One large-scale test used a 6 hp R-22 digital scroll compressor to heat a four-story apartment building in Beijing, China. The heat pump system kept the building heated with a discharge air temperature over 100°F even with the outdoor temperature below 15°F.

15.14 SCREW COMPRESSORS

Rotary screw compressors are positive-displacement machines made for large-tonnage applications. Rotary screw compressors are available in single-, twin-, and triple-rotor types. They are relatively simple in concept but demand advanced manufacturing to very close tolerances. Some of the advantages of screw compressors are as follows.

- **High volumetric efficiency** Volumetric efficiency expresses the rate of internal refrigerant leaking past the internal compressor parts. Very little of the refrigerant that enters the compressor at the suction port is allowed to slip back by the screws. Almost all of it is forced out at the discharge port.
- **High compression ratios** The compression ratio is expressed as a ratio between the absolute suction pressure and the absolute discharge pressure. A high compression ratio allows the screw to produce very cold evaporator temperatures and high condenser temperatures without damaging the compressor.
- **Positive displacement** Positive displacement means that every time the screws turn, a fixed amount of refrigerant is moved. This means that the cooling capacity changes are directly related to compressor speed. This makes it much easier for screw compressors to have a variable capacity.
- **High-pressure refrigerants** High-pressure refrigerants tend to more easily leak past internal compressor

parts. However, the screws' oil coating seals small gaps, thus keeping a high volumetric efficiency.

- **Large tonnage** Screw compressors are available in capacity up to 700 tons.
- **Variable capacity** There are a variety of ways that screw compressors can vary their capacity to meet the demands of changing loads.
- **Refrigeration or air-conditioning applications** Screws are capable of producing low-temperature refrigeration down to -40°F or air-conditioning temperatures ranging up to 45°F.

Screw compressors are available in open, semihermetic, or hermetic designs (Figure 15-39). Hermetic designs are available from 35 to 175 hp and are often used in multiples for larger capacity equipment.

A single-screw design using gate rotors is available. Single-screw compressors use a single helical main rotor and either one or two gate rotors.

The compression volume is formed by the rotor grooves, the cylinder wall, and by the meshing gate-rotor teeth. The rotor groove fills with gas, turns, and compresses the gas as the volume is reduced by the meshing action with the gate rotor. Oil flooding is used for sealing as well as lubrication and cooling.

The twin-screw models are used for larger refrigeration and air-conditioning (usually water chilling) applications (Figure 15-40). They often consist of a driven male rotor and mating female rotor carried on bearings and rotating within a stationary housing containing gas inlet and discharge ports. Either rotor can be the driven component, although it is possible to use synchronized timing gears to drive both rotors.

A triple-screw compressor is also available (Figure 15-41). It has a variable-frequency drive motor that allows it to change the motor rpm, giving the triple screw a very large operating capacity range. Both the single- and twin-type screw compressors get much louder as they are unloaded, but the triple screw gets quieter. This is a major advantage when the equipment room in a building is close to occupied spaces.

Operation of Screw Compressors

All three types of screws operate similarly. They draw the refrigerant gas in through the inlet port into voids created as the rotors turn, as shown in Figure 15-40. The entire length

Figure 15-40 Cross-section view of a twin screw showing the gas flow through the compressors.

Figure 15-41 Triple-screw compressor. (Courtesy of Carrier Corporation)

of the rotor space will fill with gas. As the rotors continue to rotate, they reengage one another on the suction end. This progressively compresses the trapped gas as they mesh, moving it toward the discharge end of the machine. The compressed gas is released through the discharge port

as the rotors turn and uncover the port. The cycle repeats as interlobe spaces are created, fill with gas, diminish (compressing the gas), and vent gas to the discharge. The individual discharges blend into a smooth flow of gas with little pulsation compared to a comparable reciprocating compressor.

Rotor bearings may be sleeve or magnetic, referred to as antifriction, depending on machine design and size. The oil separator is an important component in oil-flooded machines. The compressor could quickly run out of oil without the oil separator returning oil to the compressor. An oil separator may be built as an integral part of the design.

Capacity control is possible by speed adjustment or valves. Valve types include slot valves, lift valves, or slide valves. The most commonly used device is the slide valve. It is a simple arrangement that bypasses part of the gas back to the suction and regulates the discharge port. It permits satisfactory unloading over a wide capacity range and is an uncomplicated and reliable mechanism.

15.15 CENTRIFUGAL COMPRESSORS

Centrifugal compressors are widely used in single-stage, multi-stage, open, and semihermetic configurations to chill water for building air conditioning in capacities from 100 to 8,000 tons and higher. Centrifugal compressors are used for moving large volumes of gas against low-pressure differences. One example of a centrifugal compressor is shown in Figure 15-42. Currently, centrifugal capacities are limited to less than 1,000 tons. Larger chiller units utilize multiple compressors. These machines compete with the screw machines for large-capacity chilled-water cooling plants.

Most centrifugal systems are extremely large and used as part of a chiller system in large commercial buildings. These systems are so large that they fall under local, state, or federal guidelines for equipment room operators. An individual must be present at all times when these systems are running. Most run twenty-four hours a day, seven days a week. The individual who operates these units may be referred to as an equipment room operator or an operating engineer.

Centrifugal compressors are grouped into low-pressure and high-pressure machines. Low-pressure centrifugals work

Figure 15-42 Multistage centrifugal compressor.

at pressures ranging from an 18 in. Hg vacuum on the low side to 10 psig on the high side. Older low-pressure centrifugal machines used R-11, a CFC. Newer low-pressure centrifugals use R-123, an HCFC. High-pressure centrifugal compressors are available in both open and semihermetic configurations. They may use refrigerants such as R-134a or R-22.

TECH TIP

Most centrifugal chiller systems cannot produce more than an 18°F temperature difference in the chilled water. If a greater temperature drop in chilled water temperature is needed, two centrifugal chillers may be installed in series. In a series installation, the chilled water from the first unit is passed through the second unit, where it is cooled to a lower temperature. Two centrifugal chillers in series could produce a 36°F temperature difference in the chilled water.

Operation of Centrifugal Compressors

The impeller acts like a fan. It can move large volumes of refrigerant vapor as long as there is relatively little pressure difference between the evaporator and the condenser. Refrigerant enters in the middle of a centrifugal impeller and is thrown outward by centrifugal force (Figure 15-43). Figure 15-44 shows a precision die-cast centrifugal impeller. A two-pole 3,600 rpm motor uses a gear-type speed increaser to drive the impeller at speeds of 8,000 to 10,000 rpm and higher. To reduce sound levels, the impeller vanes are asymmetrically arranged but fully balanced.

Centrifugal compressors are not positive-displacement compressors. If there is too great a pressure difference between the evaporator and the condenser, the impeller may not be able to move refrigerant. If this happens, it may begin to surge, which can destroy the impeller. Capacity control can be accomplished by inlet vane controls or variable motor speed control. Inlet vane controls are the most common.

Centrifugal compressors were once considered low-pressure machines. Today there are many centrifugal compressors that use high-pressure refrigerants. High-pressure

centrifugal chillers are smaller than low-pressure chillers for the same capacity.

15.16 ENGINE-DRIVEN COMPRESSORS

Not all compressors are operated by electric motors. Some compressors use gas or diesel engines to drive them. The most common application of engine-driven compressors is found in transport refrigeration, where diesel engines are mated to open compressors (Figure 15-45). Engines are used out of necessity in transportation refrigeration because the system is traveling down the road.

Some large stationary chiller applications also use engine-driven compressors. These typically use natural gas engines. These systems allow efficient cooling in large applications where reducing electrical usage is a priority. The engine speed can be varied to achieve variable capacity.

Figure 15-45 Transport refrigeration compressor mounted to diesel engine.

Figure 15-46 Oil slinger on small semihermetic compressor.

15.17 COMPRESSOR LUBRICATION

All refrigeration compressors require lubrication of moving surfaces. Delivery of lubricant can be by simple splash systems or a separate oil pump. A common splash system uses a slinger that slings the oil around the inside of the compressor (Figure 15-46). A cup catches the oil and it drains by gravity into the crankshaft. The crankshaft throws the oil out by centrifugal force through holes in the crankshaft (Figure 15-47).

Pressure lubrication is used with larger compressors. Typically the oil pump is mounted on the compressor end of a semihermetic compressor (Figure 15-48). The oil pump picks oil out of the crankcase pump and forces it down the crankshaft. Holes in the crankshaft deliver the oil to the rods and bearings. Typically the oil pump is mounted on the compressor end of a semihermetic compressor.

Open and semihermetic compressors often have an oil sight glass to view the compressor oil level. The oil level should be judged with the compressor running after it has run long enough for the pressures to stabilize and the crankcase to become warm. The correct oil level will depend on the model and manufacturer, but the oil level should be above the bottom of the sight glass on most compressors. The maximum oil level will vary between three-eighths and

Figure 15-47 Oil is delivered through the holes in the crankshaft.

Figure 15-49 Oil sight glass three-eighths full.

one-half of the way up the glass on most compressors. Figure 15-49 shows an oil sight glass with the correct level for that compressor.

Some oil leaves with the discharge gas. The refrigerant must be able to carry the oil back. The oil should be miscible with the refrigerant for this to happen. System piping is also critical. The refrigerant must travel at a minimum speed to keep the oil moving with it.

Some machines are designed to have high oil circulation rates and are always provided with discharge-oil separators. Oils used in hermetic and semihermetic systems have to be compatible with the electrical components and be good insulators. Mineral oils should be wax free. All oils should have a low moisture content to ensure long, corrosion-free system life and freedom from electrical insulation deterioration and freeze-ups.

CAUTION

Refrigerant oil does not evaporate from a system. If you have a compressor that is operating on low oil, the oil is trapped somewhere in the system. Determine where the oil is and what problem has caused the oil to be entrapped in the system away from the compressor, and resolve that problem.

HFC chlorine-free refrigerants require use of special polyol ester (POE) synthetic oils. Older CFC machines used mineral oil-based lubricants. Current recommendations for HCFC refrigerant installation and conversions include mineral oil, alkyl-benzene refrigeration oil, or a combination of the two. The choices have become more complicated. POE refrigeration oil is more expensive but can be used with all halocarbon refrigerants. It must be used with HFC refrigerants as specified.

Pressure lubricated compressors are usually equipped with an oil pressure switch to shut the compressor down should lubrication fail. Oil pressure switches measure the differential pressure between the oil pressure and the suction pressure to measure actual oil pressure. They include a time delay to allow for system startup and to avoid nuisance trips. A safety lockout circuit prevents the system from restarting after shutdown. Refer to manufacturer data for minimum pressure settings, normal operating pressures, and high relief valve settings.

Oil and refrigerant liquid are miscible, so it is possible to have refrigerant migrate during long off cycles to a compressor in a cold location. The oil and refrigerant mixture raises the oil level above the oil sight glass (if so equipped),

Figure 15-50 The oil level must be visible in the sight glass.

as shown in Figure 15-50. On startup, the crankcase pressure drops, the liquid refrigerant flashes to gas, and the mixture turns to foam. The oil pump does not pump the foam effectively, and the foam is a poor bearing lubricant. Once the system has started and operated until the oil is warm, the problem clears. Where such problems are encountered, crankcase heaters can be used as well as timed pump-down cycles and piping changes. A crankcase heater can be added to the outside of hermetic compressors to raise the temperature of the oil to prevent this migration from occurring, as shown in Figure 15-51. A flat crankcase heater can be attached to the bottom of semihermetic compressors for the same purpose, as shown in Figure 15-52.

15.18 COMPRESSION RATIO

Compression ratio is the ratio of the absolute discharge pressure over the absolute suction pressure. High compression ratios can cause overheating. Compression ratio

Figure 15-51 External crankcase heater for hermetic compressors.

Figure 15-52 External crankcase heater for semihermetic compressors.

is calculated by dividing the absolute discharge pressure by the absolute suction pressure. For example, to find the compression ratio for a system with a 210 psia discharge pressure and a 70 psia suction pressure:

$$210 \text{ psia}/70 \text{ psia} = 3/1 \text{ compression ratio}$$

It is important to remember that compression ratio is calculated using absolute pressure, but your gauges read gauge pressure. The system pressures must be converted from gauge pressure to absolute pressure to calculate the compression ratio of an operating compressor. A reasonable estimate of absolute pressure can usually be obtained by adding 15 to gauge pressure. In the previous example, the discharge pressure would be 195 psig and the suction pressure 55 psig. When starting with gauge pressures, the calculation looks like this:

$$(195 \text{ psig} + 15)/(55 \text{ psig} + 15) = 210 \text{ psia}/70 \text{ psia} \\ = 3/1 \text{ compression ratio}$$

System efficiency drops as compression ratio increases. Compressors also increase in temperature as the compression ratio increases. The compression ratio should be kept as low as possible to increase efficiency and to extend life. Factors that help in keeping the compression ratio as low as possible are keeping the condenser temperature as low as possible and keeping the evaporator pressure/temperature as high as possible. However, the suction pressure is more critical than the discharge pressure.

Consider a comparison of the effects of increased head pressure and decreased suction pressure on a system operating at 240 psig discharge pressure and 70 psig suction pressure. The compression ratio is

$$(240 \text{ psig} + 15)/(70 \text{ psig} + 15) = 255 \text{ psia}/85 \text{ psia} \\ = 3/1 \text{ compression ratio}$$

If the head pressure is increased by 60 psi while the suction remains the same, the compression ratio becomes

$$(300 \text{ psig} + 15)/(70 \text{ psig} + 15) = 315 \text{ psia}/85 \text{ psia} \\ = 3.7/1 \text{ compression ratio}$$

If the head pressure stays the same while the suction pressure drops to 50 psig, the compression ratio becomes

$$(240 \text{ psig} + 15)/(50 \text{ psig} + 15) = 255 \text{ psia}/65 \text{ psia} \\ = 3.9/1 \text{ compression ratio}$$

Lowering the suction pressure 20 psi increased the compression ratio more than raising the discharge pressure 60 psi. Dirty filters, iced coils, partially restricted filter driers, and misadjusted expansion valves can all cause small

drops in suction pressure that can have a large effect on the compression ratio and system performance.

TECH TIP

It may be cost-effective to use a multistage compressor system or a cascade system when a low-temperature refrigeration system would have too high a compression ratio. The added cost of the more expensive compressors may be offset by the cost of repeatedly replacing overheated and failed compressors.

15.19 COMPRESSOR CAPACITY AND HORSEPOWER

It is common to refer to compressors by a fixed capacity—that is, 1 ton, 2 ton, and so on. However, a compressor's capacity is not a fixed value. There are many factors that affect a compressor's BTUH capacity per horsepower of input. These factors include evaporator temperature, condenser temperature, refrigerant properties, and compressor rpm.

Low Evaporator Temperatures

Less refrigerant enters the cylinder for each compression cycle at lower evaporator temperatures. Less cooling occurs when less refrigerant flows through the system. This requires more horsepower for each BTU of cooling. From 1 to 5 hp may be needed for a ton of cooling, depending on the box temperature. Examples of low-evaporator-temperature systems include medium- and low-temperature refrigeration units and heat pumps.

High Evaporator Temperatures

Higher temperatures increase the BTUH capacity, requiring less horsepower for each BTU of cooling, for example, normal and high-efficiency air conditioning.

Low Condenser Temperatures

The cooler the air or water entering the condenser, the greater its heat-removal capacity. This results in lower condenser pressures, and the compressor has to do less work. This reduces the horsepower required for each BTU of cooling. Air conditioners that are used to cool equipment rooms even in the fall or spring provide higher cooling capacities with less energy or horsepower used.

High Condenser Temperature

The higher the condenser temperature, the harder a compressor has to work to move the refrigerant vapor out of the evaporator into the compressor. This requires more horsepower for each BTU. It is much like driving up a steep hill requires more horsepower for a given speed than does driving at the same speed on nearly level roads. Air conditioners in the southwestern states experience the high summer desert temperatures. But rooftop air conditioners may experience similar temperatures through much of the United States.

Refrigerant Properties

Each refrigerant type has unique chemical properties that affect a compressor's capacity.

Compressor RPM

Most compressors operate on 60 or 50 cycle incoming power. The frequency of the power supply affects the compressor's rpm and therefore its pumping capacity.

Horsepower versus Capacity

There are a few generalizations that can be given regarding horsepower and BTUH capacity. For normal condenser operating temperature ranges, the lower the evaporator temperature, the more horsepower required to produce the same BTUH capacity. The following general rule of thumb can be helpful as a starting point.

- **Air-conditioning temperatures** 1 hp per ton of cooling
- **Medium-temperature refrigeration** 1 hp per two-thirds ton of cooling
- **Low-temperature refrigeration** 1 hp per one-third ton of cooling

Low-temperature refrigeration may take 3 or more horsepower to produce 1 ton of cooling depending on the box temperature and outside air temperature. Refrigeration compressors can be very large compared to air-conditioning compressors with the same ton capacity.

The intake ports on low- and medium-temperature compressors are larger in size than the intake ports on air-conditioning compressors. They have to be larger to allow enough low-density, low-pressure refrigerant vapor into the compression cylinder. If a compressor is used on a higher-temperature system it will take in too much refrigerant for each compression cycle. This will result in the compressor overheating and failing—that is, a low-temperature compressor cannot be used on a medium-temperature or air-conditioning application, nor can a medium-temperature compressor be used on an air-conditioning application.

The smaller intake ports on air-conditioning or medium-temperature compressors will not allow enough refrigerant to enter the compressor cylinder if they are used on a low-temperature application. Too little cool refrigerant entering the cylinder will cause the compressor to overheat, too.

TECH TIP

When you buy a hermetic compressor you are buying both a motor and a compressor. The size and type of motor you need will change depending upon what you are asking the compressor to do. For this reason, hermetic and semihermetic compressors are classified by the saturation temperature of the suction gas entering them and the type of refrigerant they are designed to handle. Never use a compressor for an application for which it is not intended to be used.

15.20 CAPACITY-CONTROL FACTORS

Compressor capacity control refers to controlling how much work the compressor can perform. The idea of capacity control is to make the compressor capacity match the load. The energy required to operate the compressor is minimized by matching the compressor capacity to the load because an unloaded compressor uses less power than a fully loaded compressor. A compressor that runs continuously at reduced capacity will draw fewer total watts of power than one that starts and stops while running at full capacity.

Capacity control also improves building comfort. Many large buildings have a latent load that must be maintained even when there is a light load on the building. By providing this unloading capacity, the system can run in what is sometimes referred to as background so that the air is dehumidified without significantly cooling it.

There are a variety of ways of changing compressor capacity to match system load:

1. Cycling multiple compressors on and off
2. Cylinder unloading
3. Hot-gas bypass
4. Speed control
 - a. Two speed
 - b. Variable-frequency drives (VFD)

Multiple compressors with either common or independent refrigerant circuits are sometimes used. A twin compressor installation would give the choice of 0, 50, and 100 percent capacity steps (Figure 15-53).

Figure 15-53 Capacity control by using two compressors on a common refrigerant circuit.

Figure 15-54 The standard head is on the left; the head with the unloader is on the right.

Cylinder unloading is available on reciprocating compressors with multiple heads. Compressor unloaders can be actuated by gas, by oil pressure, or electrically. They can unload one or more cylinders by holding the suction valves open, bypassing the cylinder discharge to the suction manifold, or blocking off the suction inlet.

Figure 15-54 compares a normal compressor head and a head with an unloader. When the unloader is energized, gas passes from the high side of the head to the low side of the head, eliminating any work from that head.

Depending on the compressor, multiple stages of control can be provided and power savings achieved. The number of steps depends upon the number of heads. A three-head compressor can have steps of 33, 66, and 100 percent.

Hot-gas bypass is sometimes used on small machines where cylinder unloading is unavailable or on larger machines when additional capacity reduction is required. With hot-gas bypass, some of the compressor discharge gas is piped back into the suction of the compressor. Care must be taken not to overheat the compressor. It can be a practical solution in dealing with light loads. This process is not energy efficient.

Some compressors are available with two-speed motors. This technique (two-speed control) is not widely used at present. Single-phase compressors change speed by switching from a four-pole motor on low speed to a two-pole motor on high speed. Three-phase motors change speed by changing from a wye arrangement on low speed to a delta arrangement on high speed. Wye arrangements join the three windings together in the center to form a Y shape. Delta arrangements join the three windings together to form a triangle, or delta shape. Typically, an arrangement of contactors controls the speed of the compressor motor. These types of compressors must shut down to change speeds.

Variable frequency drives (VFD) enable continuous variable speed (capacity) control on many machines. These have been applied to large centrifugal compressors as well as to smaller comfort cooling applications. Variable speed control works very well and is likely to be increasingly used as the cost of VFDs (also called inverters) continues to drop. It can be very energy efficient.

Brushless DC motors offer a very efficient way of controlling compressor motor speed and system capacity. Two types are currently used: electronically commutated (ECM) and switched reluctance. Currently only a few very small fractional horsepower hermetic compressors use ECM technology. Compressors up to 5 hp are available with switched reluctance drive. These motors do not have a starting current surge but ramp up slowly to avoid inrush current.

Slide valves are commonly used on screw compressors to regulate capacity. The valves work well and save energy. They function based on diverting gas to the suction manifold before it is compressed.

Inlet vane capacity controls are commonly used on centrifugal chillers. These vanes can control down to 10 to 25 percent capacity. They function by giving the entering gas a pre-rotation swirl.

15.21 TROUBLESHOOTING THE COMPRESSOR

Compressors built today are expected to provide many years of constant, trouble-free, quiet operation. In many applications, the compressor is required to run twenty-four hours per day, 365 days a year. Continuous operation is not as hard on a compressor as is cycling operation, because oil temperature and viscosity constantly change during cycling operation.

CAUTION

Some INCORRECT procedures used in the past for testing compressors recommended that the suction line service valve be closed to see how deep a vacuum the compressor would pull. DO NOT use this procedure! It can result in deep vacuum, which can allow internal arcing to occur in the electrical windings of the compressor. This practice is NOT recommended by any refrigerant compressor manufacturer and must not be performed. It can result in compressor failure.

The compressor must not only be designed to withstand normal operating conditions but also occasional abnormal conditions such as liquid slugging and excessive discharge pressure. Compressors have been designed to take extra punishment and yet function properly. Most compressor failures are caused by system faults and not from operating fatigue. The degree of skill used by the technician to install, operate, and maintain the equipment will ultimately determine the actual life of the system, particularly the compressors. It is therefore helpful to review some of the factors that shorten the life of a compressor.

Compressor failures can be grouped into two general categories: mechanical failure and electrical failure. Sometimes a mechanical failure will lock the compressor, causing it to burn out the motor, thus looking like an electrical failure. This may cause a technician to overlook the true cause of this mechanically/electrically failed compressor. The result can be that the uncorrected mechanical problem

will cause replacement compressors to fail in a similar manner. Only the mechanical failure problems will be covered in this unit.

The most common mechanical failures include liquid refrigerant floodback, liquid refrigerant slugging, oil slugging, flooded starts, high discharge temperature, and loss of lubrication. Many of these mechanical failures can be diagnosed by disassembling and inspecting the failed compressors. System operational diagnosis can often locate the cause of these problems. A thorough check of the system operation should always be performed after replacing a failed compressor.

SERVICE TIP

If a compressor had both a mechanical and electrical failure, you can bet the mechanical failure occurred first. There is virtually no way that an internal mechanical failure can occur once a compressor fails electrically. If you have both types of failures, look for the cause of the mechanical failure. The electrical failure is probably only a secondary failure resulting from the mechanical problem.

15.22 LIQUID REFRIGERANT FLOODBACK

Liquid refrigerant floodback occurs while the system is operating. A system operating with a suction line superheat of 5° or less is probably experiencing flooding. This can be caused by dirty air filters, dirty or iced evaporator coils, inoperative evaporator fan motors, overfeeding expansion valves, or overcharged systems.

Oil Dilution

Liquid returning to the compressor does damage, even if the compressor does not immediately drop dead. Small amounts of liquid dilute the oil. This oil-refrigerant mixture is not as good a lubricant as the oil alone. This causes premature bearing failure. Any liquid that reaches any lubricated part of the compressor effectively washes off the lubrication and causes excess wear. Figure 15-55 shows the result of oil dilution.

Figure 15-55 Bearing surface is worn due to oil dilution.

Figure 15-56 Liquid slugging can break internal compressor parts.

Liquid Slugging

If large amounts of liquid are returning in the suction line, some of it may make it into the cylinder space. Liquid does not compress. If the liquid cannot leave quickly, the mechanical force is quickly converted into thousands of pounds of hydraulic pressure, and something will break. Broken valves, valve plates, rods, or crankshafts are all symptoms of liquid slugging. Figure 15-56 is an example of the damage that can be done with liquid slugging.

Oil Slugging

Oil slugging does the same type of damage that liquid refrigerant slugging does. It is caused by the sudden return of large amounts of refrigerant oil. This usually indicates a refrigerant piping problem or system issue. Suction lines with large traps can fill with oil and then send it back in one burst. Systems operating at reduced capacity for long periods of time are more likely to trap out oil in the lines.

15.23 FLOODED STARTS

Refrigerant dissolves in the oil during the off cycle. System arrangement and location can play a part in allowing large quantities of refrigerant to migrate into the oil in the compressor while it is shut down. When the compressor starts, the refrigerant boils out violently, creating a foamy refrigerant-oil mixture. This is similar to what happens when you shake a carbonated beverage and then open it. This foam can fill the crankcase and make its way into the cylinder. Enough foam in the cylinder will cause hydraulic pressure and break parts. Off-cycle migration can be minimized with crankcase heaters and pump-down cycles.

15.24 COMPRESSOR OVERHEATING

All compressors get hot while working. The lower the saturation temperature of the suction gas, the hotter the compressor gets. One reason for this phenomenon is the amount of

Figure 15-57 Compressor heads should not be discolored; this head shows the effect of high discharge temperature.

energy required to move heat at a low temperature level up to a much higher temperature level. It takes a lot of mechanical energy to do this work.

There is a limit to how hot a temperature the internal parts of a compressor can withstand. Internal compressor parts can be damaged due to the high temperatures. The oil used to lubricate the compressors starts to fail around 300°F. It is critical to keep the internal compressor temperature below 300°F to avoid certain damage. The compressor internal temperature is approximately 50–75° higher than the discharge line temperature. A compressor operating at excessive temperatures can be diagnosed by measuring the discharge line. The maximum discharge line temperature should be between 180°F and 220°F. A compressor operating at or above these temperatures is living on borrowed time. Varnished oil deposits on the head and valve plate indicate that this system has been operating at consistently high temperatures (Figure 15-57).

Excessive operating temperatures are caused by having too little refrigerant entering the compressor. This can be because of system charge, a refrigerant restriction in the system, or a misadjusted metering device.

15.25 OIL FAILURE

Oil failure can occur when internal compressor parts reach temperatures in excess of 300°F. At temperatures ranging from 315°F to 325°F, many refrigerant oils do not provide adequate lubrication. At a temperature of 350°F and above, most refrigerant oils begin to break down chemically. *Carbonization* is the term used to describe the formation of free carbon in refrigerant oil. Free carbon in overheated oil is what makes the oil look black in color. When oils carbonize they lose most of their ability to lubricate moving parts.

SAFETY TIP

Compressor oil may contain acid. This is especially true of oil that has been overheated. Care should be taken when handling the oil from a failed compressor, because the acid can cause serious burns.

TECH TIP

Polyol ester oils (POE) are clear but over time may turn from a light straw color to a darker brown. This does not mean the oil is carbonizing but simply that the oil's protective additives are becoming activated.

15.26 LOSS OF EFFICIENCY

The loss of efficiency of a compressor is usually an indication that the compressor is being subjected to system problems that are wearing some of the component parts. For a reciprocating machine, this can result from a number of conditions.

Leaking Valves

A reciprocating compressor with leaking valves cannot maintain the desired pressure difference. A high suction pressure and low discharge pressure are the most common symptoms. The compressor gets hot because the amount of refrigerant circulated is less. The amp draw is low because the compressor is doing less work. The system superheat is high and the system subcooling low.

Blown Head Gasket

Liquid in the clearance space can force its way from the high side to the low side by making a new path through the head gasket. This has the same effect as leaking valves.

Worn Wrist Pins, Rods, and Bearings

Systems that have leaking discharge valves or blown head gaskets will eventually develop problems in their piston wrist pins and rods. Gas leaking by the discharge valves puts continual downward pressure on the pistons. This prevents oil from getting in the spaces at the top of the bearing surfaces, so these surfaces wear. The holes elongate, causing slop in the piston action (Figure 15-58). When a compressor with this problem starts, it is very noisy until the head pres-

Figure 15-58 Elongated rod was caused by constant pressure on top of the piston because of leaking discharge valves.

sure builds up. Worn bearings, especially loose connecting rods and wrist pins, prevent the pistons from rising as far as they should on the compression stroke. This has the effect of increasing the clearance volume and results in excessive reexpansion of refrigerant vapor in the cylinder.

15.27 MOTOR LOADING

When the compressor is not performing satisfactorily, the motor load sometimes provides a clue to the trouble. Either an exceptionally high or exceptionally low motor load is an indication of improper operation. Mechanical problems such as loose pistons, improper suction valve operation, or excessive clearance volume usually lead to reduction in motor load but an increase in motor temperature. Another common problem is a restricted suction chamber or inlet screen (caused by system contaminants). The result is much lower actual pressure in the cylinders at the end of the suction stroke than the pressure in the suction line as registered on the suction gauge. If so, an abnormally low motor load will result.

Improper discharge valve operation, partially restricting ports in the valve plate (which do not show up on the discharge pressure gauge), and tight pistons will usually be accompanied by high motor load. Abnormally high suction temperatures created by an excess heat load will cause a high motor load. Abnormally high condensing temperatures, created by problems associated with the condenser, will also lead to high motor load. Low voltage at the compressor will cause high amp draw and overheated motors.

15.28 COMPRESSOR CHANGEOUT

Compressor changeout is considered one of the more important and difficult jobs a service technician will perform. This is because the compressor is the most expensive component and because so many electrical and refrigeration skills are required in order to change a compressor. There are several steps involved in replacing a hermetic compressor that involve procedures covered in other units. References to these procedures will be included. For safety, you should first disconnect and lock out power to the unit (Unit 32). Use an electric meter to test for voltage at the unit to be sure the power is off (Unit 35). It is also a good idea to discharge the compressor run capacitor since the run and start wires to the compressor are connected to the start and run terminals of the compressor (Unit 37). Recover the system refrigerant (Unit 28).

On larger systems with both suction and discharge service valves, the valves can be front seated to isolate the compressor so that you only need to recover refrigerant from the compressor. After the refrigerant has been recovered, the piping connections to the compressor are either cut out or unbrazed. Cutting the lines to the compressor is recommended because it is both safer and cleaner. Use a tubing cutter to avoid creating chips that can fall into the lines. Try to cut as closely to the compressor as possible. Oxides that can contaminate the new compressor are formed inside the tubing when the compressor is unbrazed. Technicians have been severely burned by unbrazing a compressor that still had a refrigerant charge. Even a compressor without a

refrigerant charge will push out a small flame spout when the tubing is pulled free.

Next, physically remove the compressor and mount the new compressor. Remove the caps or plugs holding the nitrogen charge in the new compressor and connecting the system tubing. To avoid allowing air and moisture into the new compressor, the caps should not be removed until just before the new connections are made. If the replacement compressor is not an exact match, you may need to fabricate some tubing to make the connections between the compressor and the existing tubing. The connections should be nitrogen brazed to reduce oxide formation (Unit 25). Ideally, driers should be installed on both the suction and liquid lines. On severely contaminated systems, the lines may need to be flushed first. (See Unit 91 for more details on system cleanup.) After the compressor and filter driers are connected, the system should be leak tested (Unit 29), evacuated to below 500 microns (Unit 30), and charged according to the manufacturer's recommendations (Unit 31).

UNIT 15—SUMMARY

Compressors are vapor pumps. The compressor's job is to raise the pressure and temperature of the refrigerant so that it can be condensed. Together, the compressor and the metering device create the high side and low side of the refrigeration system. Compressors may be classified by their general operating principle, physical enclosure, mechanical design, cooling mechanism, and evaporator saturation temperature. The different compressor mechanical designs include reciprocating, rotary, scroll, screw, and centrifugal.

All types of compressors work by reducing the gas volume. Reciprocating compressors use pistons moving up and down in cylinders, rotary compressors use a rolling piston orbiting in a cylinder, scroll compressors use a movable scroll orbiting inside a fixed scroll, screw compressors use helical screws meshing together, and centrifugal compressors use a high-speed impeller that throws the refrigerant outward using centrifugal force.

Compressor enclosure types include open, hermetic, and semihermetic. Open compressors are driven by an external motor and have a shaft seal. Both the compressor and the motor are enclosed in hermetic and semihermetic compressors. Hermetic compressor shells are welded together, while semihermetic compressor housings are bolted together. Hermetic compressors are cooled by the refrigerant; semihermetic compressors are cooled by either refrigerant or air.

Common mechanical compressor problems include liquid refrigerant floodback, liquid refrigerant slugging, oil slugging, flooded starts, high discharge temperature, and loss of lubrication. Most compressor problems are caused by system problems. If the system problem that caused the initial failure is not corrected, repeat failures are certain. Technicians should analyze failed compressors to determine the cause and then check the system to eliminate the cause of the compressor failure.

Service Ticket 1501

Customer Request: Compressor Replacement

Equipment Type: R-410a Split Refrigeration System

A customer has a 3-ton scroll compressor that was almost new when it was removed from the building's air-conditioning system during remodeling last year. The compressor has been sealed and kept dry. They want you to install it on their walk-in cooler. The cooler is operated at 30°F, and the condenser is located in the storage room, which is kept at a constant 80°F. You check the box heat load and see that it was calculated to be 35,000 BTUH.

The customer looked up the compressor data on the Internet. They point out to you that the compressor has slightly more capacity with a 30°F evaporator temperature and with an 80°F condensing temperature than the box load. The customer then asks you, "Can you use the compressor?"

You tell them no. You explain that the evaporator temperature for a walk-in cooler will have to be 10°F to 20°F below the box temperature. That would mean that the evaporator temperature would have to be somewhere between 10°F to 20°F, and according to the chart, it would produce between 23,200 to 28,800 BTUH—not enough to keep the walk-in at 30°F.

But most important, you tell them that the scroll they have is for air conditioning and they need a refrigeration compressor. The compressor looks like the old one on the walk-in, but internally it is much different. It would not last very long if installed in a refrigeration application.

Service Ticket 1502

Customer Complaint: Compressor Shutting Off

Equipment Type: R-22 Commercial Refrigeration System with a Semihermetic Air-Cooled Compressor

The customer tells you that the compressor keeps tripping on the low-pressure cutout. They tell you that they know it is working just fine because the evaporator keeps making a good layer of ice between defrost cycles.

You check the system pressures and see that the evaporator is 20 psi below the designed operating pressure/temperature. On investigation you see that one of the evaporator fans is out. You change the fan, and the system pressure returns to its normal reading.

After learning from the customer that they had been pushing the low pressure cutout reset button for months before calling you, you tell them you want to check the refrigerant oil. The customer does not understand why that is necessary because the level is OK in the sight glass.

You explain that you are concerned that the compressor may have been overheated and that overheating can result from too low an evaporator temperature. After a brief explanation of compression ratio and overheating, they agree to let you do the additional work.

Upon investigation, you find the oil to be black and slightly acidic. You follow the manufacturer's recommendation to change the oil and deacidify the system. Several months later, while back on a different system service call, you see this compressor is still running well. You know your oil change and deacidification kept it going.

Service Ticket 1503

Customer Complaint: Poor Cooling Capacity

Equipment Type: R-22 Air-Conditioning System with a Hermetic Reciprocating Compressor

You are called to look at a residential air-conditioning system that is not cooling properly. The airflow across the evaporator is very low. The customer suggests that the system may need a charge because another technician added refrigerant two months ago when the evaporator coil was freezing up. The evaporator is not frozen, but the coil is so packed with dirt that the fins are not visible. You clean the evaporator coil and change the air filter. With proper airflow, the temperature drop across the evaporator is only 8°F. The suction pressure is 95 psig, the head pressure is 150 psig, the compressor body is hot, and the amp draw is low. You conclude that the compressor valves are damaged, reducing the pumping capacity of the compressor. Most likely, the damage was caused by liquid slugging as a result of poor airflow and overcharging.

Service Ticket 1504

Situation: New System Startup

Equipment Type: R-410a Rooftop Three-Phase System with a Scroll Compressor

You are asked to start a new R-410a rooftop air conditioner. The system operates on three-phase power. On initial startup, the compressor makes a loud rattling noise. You notice that the pressures are still equalized and the condenser fans appear to be running backward. You shut down the system to avoid compressor damage, swap L1 and L2 at the power lug on the unit, and restart the system. The compressor noise has disappeared, the pressures look normal, and the fans are running the right way. You conclude that two of the three-phase power legs were swapped, causing the three-phase motors to run backwards. Since scroll compressors only work in one direction, the compressor could not pump running backwards.

Condensers

OBJECTIVES

After completing this unit, you will be able to:

1. explain how air-cooled and water-cooled condensers work.
2. list the types of air-cooled condensers.
3. list the types of water-cooled condensers.
4. explain why it is important to keep the condenser clean.
5. compare the operation of an air-cooled condenser to a water-cooled condenser.
6. tell how to keep a cooling tower working efficiently.
7. calculate the heat rejected by a cooling tower.

16.1 INTRODUCTION

The purpose of a condenser coil is to reject unwanted heat from a refrigeration or air-conditioning system. It does this by condensing the high-pressure, high-temperature gas to a liquid. That is where the name *condenser* comes from; it describes what is happening inside it. For residential and light commercial split systems, the condenser coil is usually a part of the unit containing the compressor. This combination of compressor and condenser coil is referred to as a condensing unit.

16.2 CONDENSER OPERATION

The condenser is located on the discharge side of the compressor, as shown in Figure 16-1. The superheated refrigerant vapor enters the top of the condenser from the

compressor and leaves the condenser as subcooled liquid refrigerant.

The function of the condenser is to transfer heat that has been absorbed by the system to air or water. In an air-cooled condenser, the outside air passing over the condenser surface dissipates the heat to the atmosphere. In water-cooled condensers, water is used to cool the condenser. The water may either be wasted or recirculated. Because of environmental concerns regarding wasting water, most of the cooling water today is recirculated by pumping it to a cooling tower, where the heat is transferred to the atmosphere by means of evaporation.

The pressure-enthalpy diagram shown in Figure 16-2 illustrates the action performed by the condenser. The hot discharge gas from the compressor is superheated when it enters the condenser. The superheat must be removed first before the refrigerant can condense. This occurs in the first

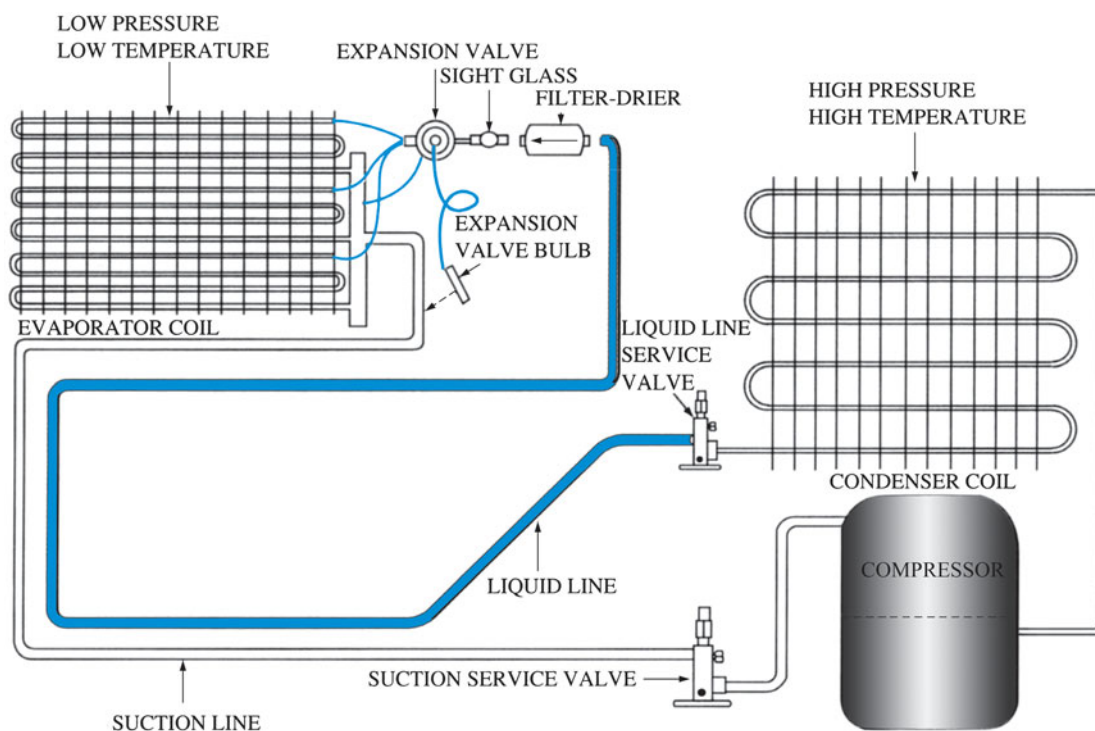

Figure 16-1 The condenser is the first major component after the compressor.

Figure 16-2 Heat removed from the refrigerant in the condenser.

portion of the condenser, known as the desuperheating section. Approximately 15 percent of the heat is removed here. Then the vapor is condensed throughout most of the condenser. Approximately 80 percent of heat is rejected through condensation. After all the vapor is condensed to liquid, the liquid is subcooled in the last portion of the condenser. Approximately 5 percent of the heat is rejected during subcooling.

Even though the subcooling accounts for only a small amount of the total heat rejection, it is important for two reasons:

- It ensures that a solid stream of liquid will enter the metering device.
- It adds to the cooling capacity of the system at a rate of about 0.5 percent of the total cooling capacity per degree of subcooling. For example: with 10°F of subcooling, 5 percent ($0.5\%/^{\circ}\text{F} \times 10^{\circ}\text{F} = 5\%$) additional capacity is added to the system.

SERVICE TIP

It is very important that air-cooled condenser coils be kept clean, as dirt does build up on them. Dirt reduces the airflow and can act as an insulator, preventing heat transfer. Condenser coil cleaning should be part of a seasonal startup program. The coil must be cleaned with an appropriate solution to remove the dirt and debris. Failure to use a manufacturer-approved solution can result in damage to the coil. Extremely dirty air-cooled condenser coils can result in very high head pressures. If the head pressure and temperature get too high, the refrigerant can decompose, forming acids. Dirty coils result in high utility usage and less cooling.

16.3 TYPES OF CONDENSERS

Three types of condensers are used with HVAC/R systems:

- Air cooled
- Water cooled
- Evaporative, which is a combination air and water cooled

A condenser is a very useful application of a heat exchanger. The condenser has to be able to dissipate or expel all of the heat picked up in the evaporator plus heat from the compressor. Heat exchangers are made of metal to permit fast and efficient heat transfer. The hot refrigerant vapor is in contact with one side of the heat exchanger surface, and the transfer medium, such as air or water, is on the other side.

The application of an air-cooled condenser is usually the simplest arrangement, particularly if the condenser is located outside. Although the water-cooled condenser is more efficient, it is more costly to install. The examples that follow demonstrate some of the common uses of condensers.

16.4 AIR-COOLED CONDENSERS

Air-cooled condensers are commonly used for residential air-conditioning systems up to 5 tons and commercial systems up to about 50 tons in capacity. Air-cooled condensers give off heat to the air and are normally located outdoors. However, the condenser is part of the appliance on small systems like refrigerators and some medium-sized commercial refrigeration systems. These systems expel the heat to the air surrounding them. At normal peak load conditions, the temperature of the refrigerant in the condenser is 25°–30°F higher than ambient temperature. This means that on a 95°F day, the condensing temperature is between 120° and 125°F.

Air-cooled condensers can be part of a packaged system that contains all the refrigeration components in one cabinet; they can be part of a condensing unit that contains the compressor, condenser, and condenser fan in one unit located outside, or they can be a separate component in a location separate from all the other refrigeration components.

The airflow across an air-cooled condenser can be natural draft, forced draft, or induced draft. Natural-draft condensers have no fan and rely entirely on natural convection and radiation. The condenser on the back of a non-frost-free refrigerator is a natural draft condenser (Figure 16-3).

Figure 16-3 Example of a natural-draft air-cooled condenser.

Figure 16-4 The fan pushes air across a forced-draft condenser.

Forced-draft condensers use a fan to push air across the condenser. The cup of the fan blade faces the condenser on a forced-draft condenser (Figure 16-4). Induced-draft condensers use a fan to pull air across the condenser. The cup of the fan on an induced-draft condenser faces away from the coil (Figure 16-5).

16.5 AIR-COOLED CONDENSERS IN PACKAGED UNITS

One common use of the air-cooled condenser is for domestic refrigerators and upright freezers, as shown in Figure 16-6. The condensers are located in the lower part of the cabinet, and a small fan is used to pull room air over the surface of the condenser coil and exhaust it back out into the room. Some refrigerators use a natural-draft-type condenser coil on the back of the cabinet.

Packaged room coolers and through-the-wall air conditioners both use air-cooled condensers. These units are manufactured in sizes ranging from $\frac{1}{2}$ to $3\frac{1}{2}$ tons of cooling capacity. They are commonly used in houses, apartments, townhouses, condominiums, offices, schools, and motels.

Another application of the air-cooled condenser is in the residential and commercial packaged air-conditioning unit (Figure 16-7). Residential package units are available

Figure 16-5 The fan pulls the air across an induced-draft condenser.

for central air conditioning in sizes from 1½ to 5 tons of cooling capacity. Commercial packaged units can be much larger sizes, ranging up to 300 tons.

16.6 AIR-COOLED CONDENSERS IN CONDENSING UNITS

The residential condensing unit is a popular use of air-cooled condensers. This unit includes the compressor, condenser, fan, and outdoor circuitry, as shown in Figure 16-8. Refrigerant lines connect to an evaporator coil located on the top of a forced-air furnace indoors or to a fan coil unit. They use ambient air to remove heat from the condenser.

These units are called split systems because they consist of two parts: an outdoor condensing unit and an indoor blower coil.

Commercial field-assembled air-conditioning systems often have a remote air-cooled condensing unit. The portion of this system inside the building is primarily an air-handling unit, including the evaporator, the metering device, and a blower-filter unit. The portion on the outside includes the compressor, condenser, and condenser fan. This type of system can be labeled a split system because it is similar to the residential split systems, except larger.

(a)

(b)

Figure 16-9 Typical remote air-cooled condenser application.

16.7 REMOTE AIR-COOLED CONDENSERS

The air-cooled condenser can be installed as a separate component in a remote location, away from all the other refrigeration components (Figure 16-9). With this arrangement, the compressor is placed inside the building out of the weather, where it will last longer. This is popular with ice machines. Ice machines with remote condensers avoid exhausting more heat into the kitchen, which is already a very warm place. The two lines going from the system to the condenser are the discharge line and the liquid line. They are both high-pressure, high-temperature lines and are normally not insulated. Occasionally the liquid line is insulated if it is run a long distance through a very hot space.

16.8 AIR-COOLED CONDENSER CONSTRUCTION

Air-cooled condensers are made of tubing with fins added to the tubing to increase the surface area in contact with the air. This is done to help accelerate the heat transfer rate

Figure 16-10 A copper tube and aluminum fin coil is shown on the left; a spine-fin aluminum coil is shown in the middle, and a micro-channel coil on the right.

out of the tubes when cooling the refrigerant. Air is not a good a conductor of heat. By adding tight-fitting aluminum fins to the refrigerant circuit's tubes, the air side surface and heat transfer can be greatly increased. The three most common constructions are copper tubing with aluminum fin sheets, aluminum tubing with aluminum "spine fins" that are wrapped around the tubing, and microchannel aluminum tubing with aluminum fins. Figure 16-10 shows an example of each type.

Copper Tubing with Aluminum Fin Coil Construction

To ensure good heat transfer, the fins must be tightly mechanically bonded to the tubes. The tighter the bond, the better the heat can be conducted to the fins from the refrigerant tubing and refrigerant. The fins are pre-stamped from thin sheets of metal, usually aluminum. They may be left flat or embossed, forming curves or waves in their surfaces (Figure 16-11). The embossed fins create turbulence in the air as it travels over the coil. This improves heat transfer by increasing the contact between the air and the coil. The fin sheets are stacked with even spacing on the copper tubing. The tubes are then mechanically or hydraulically expanded into the tube collar. Figure 16-12 shows the manufacturing process of expanding the tubes within the fin sheets.

Air-cooled finned condenser coils can be flat, U-shaped, square, or round. The coils are made flat and then formed into the desirable shape with large hydraulic presses. Some fin coils are actually two separate coils tightly formed together.

Figure 16-11 The coil on the left uses straight fins; the coil on the right uses wavy fins.

Spine-Fin Coil Construction

The other major system for manufacturing coils is to wrap aluminum fins around aluminum tubing. This produces a coil that has a prickly, or spine-like, look—thus their name, spine-fin coils. The aluminum fins for these coils are long, thin strips of aluminum with slits. This material is wrapped around the aluminum tubing to produce tubing with spine fins (Figure 16-13). This tubing is then formed into round or square coils that resemble a slinky. Several of these are stacked on top of each other to produce multisection coils, and the coils are glued together in the corners (Figure 16-14).

Microchannel Coil Construction

Microchannel coils have been used for many years in the automotive industry, but they are relatively new in HVAC systems. They are made from ribbons of aluminum, with several small passages through them called microchannels. Fins zig-zag between the ribbons. Figure 16-15 shows the construction of a microchannel coil. Because microchannel coils are more efficient than traditional tube-and-fin coils, microchannel condensers are considerably smaller than tube-and-fin condensers of the same capacity (Figure 16-16).

SERVICE TIP

Microchannel coil condensers hold less refrigerant than comparable capacity tube-and-fin coils because they have much less internal volume. The refrigerant charge for a microchannel system can be half the charge of a similar tube-and-fin system.

16.9 HIGH-EFFICIENCY CONDENSERS

Due to changes in federal law regarding the minimum SEER and EER for air-conditioning systems, manufacturers are being required to design higher-efficiency condensers. There are several ways that an air-cooled condenser can be made more efficient. Three common methods are as follows:

- Increase the coil size to increase the heat-transfer area.
- Increase the airflow rate to remove more heat.
- Decrease the condenser tube size so that more tubing can be added, which increases the heat-transfer rate.

In most cases, the higher-efficiency condensers will be larger in size than a comparably sized lower-efficiency condenser. Figure 16-17 shows a 2-ton 10-SEER air-cooled condenser and a 2-ton 13-SEER condenser side by side. This size increase must be considered when replacing an existing system. Make sure the new condenser will fit in the old condenser's spot. Some manufacturers have switched to

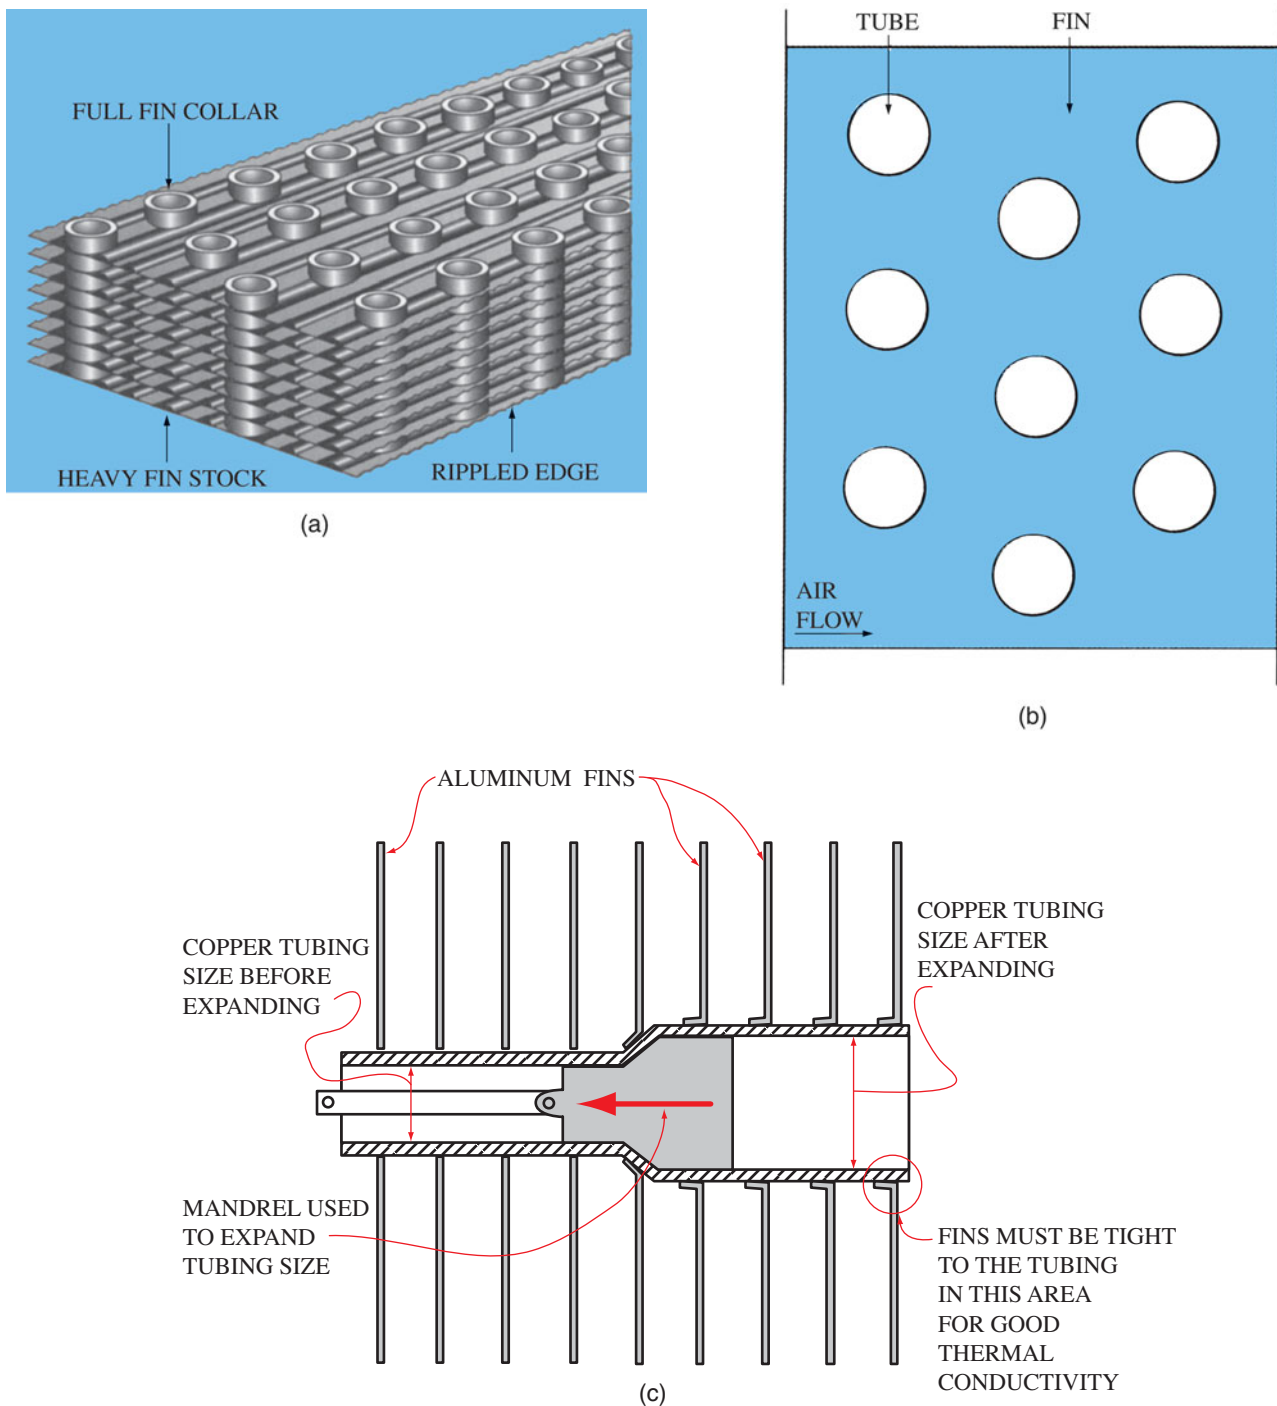

Figure 16-12 Plate-fin coil details: (a) four-row coil construction; (b) staggered tubes; (c) cross-section of finned tube assembly.

microchannel coils to keep the condenser sizes smaller on high-efficiency units.

16.10 LOW AMBIENT CONTROL

In the case of both commercial refrigeration and commercial air conditioning, low ambient operation is an important requirement. Many air-conditioning and refrigeration systems must operate when the outdoor temperature is low

because of building heat loads. Restaurants, computer labs, hospitals, and office buildings all have excessive indoor heat loads, which require cooling even in cold weather. High internal heat loads from people, lights, and electronic equipment may demand cooling even when outside temperatures go down to 35°F. Low ambient controls are essential for these systems.

Operating an air-cooled condenser at low ambient temperatures can drastically reduce the system high-side pressure. If the drop in pressure is too severe, the metering

Figure 16-16 The smaller microchannel coil is the same capacity and SEER as the larger traditional tube-and-fin coil. (Delphi Thermal Systems)

device will not feed correctly. Low ambient operation can cause a drop in system capacity. Most metering devices will feed too little refrigerant when the pressure drop across the metering device is lower than the system design pressure differential. In a normal air-cooled condenser operating between 80°F and 115°F ambient, condensing pressures are sufficiently high. But in winter, condensing pressures can drop 100 psi or more, thus the pressure across the expansion device may be insufficient to maintain control of liquid flow. Evaporator operation becomes erratic.

Systems with fixed-restriction-type metering devices are most affected by low head pressure because they have no means of adjusting to changing conditions. When the pressure difference falls, the flow of refrigerant is severely reduced. At outdoor temperatures of 65°F and lower, systems with fixed restrictions and no head pressure control cannot operate reliably. Even systems with standard thermal expansion valves can adjust only so far. Low ambient temperature can cause thermal expansion valves to underfeed as well.

The solution to the problem of low ambient operation is to maintain a minimum head pressure to ensure proper feeding of refrigerant to the evaporator. There are several different ways of doing this. The most common are fan cycling, fan speed control, damper control, and condenser flooding.

Figure 16-18 A “close on rise of high pressure” switch with an adjustable differential can be used to cycle condenser fans.

The use of improved expansion devices is reducing the need for head pressure control in some systems. Head pressure controls force the system to work as if it is 95°F outside all the time. Improved metering devices that can regulate with very low pressure drop reduce the need for head pressure control and save energy by allowing the system to operate against lower head pressures.

16.11 FAN-CYCLING LOW AMBIENT CONTROL

Where multiple condenser fans are employed on a single coil, the control system of the condensing unit can be equipped with devices to switch or cycle off the fans in stages. These controls are usually “close on rise” thermostats that measure outdoor ambient temperature or “close on rise” pressure controls that sense actual head pressure (Figure 16-18). The airflow across the coil is reduced as fans are turned off. Condensing temperatures rise with the reduced airflow. Under very low ambient conditions, all of the fans can be turned off.

One disadvantage of fan cycling is that the condenser pressure can swing rapidly between the low and high set points of the fan control. Although the system works with these swings in pressure, they can result in a loss of efficiency. Another disadvantage is that on windy days, even with the fans off, there may be too much cooling of the condenser to maintain minimum high-side pressure for the system to work properly.

Systems with a single condenser fan are generally not good candidates for fan cycling because of undesirable pressure swings. Fan cycling should never be used with air-cooled compressors if there is only one fan. Air-cooled compressors depend on the airflow across them to stay cool, so shutting off the fan, even at low ambient temperatures, can overheat an air-cooled compressor.

16.12 FAN SPEED CONTROL

Where only one condenser fan is used, air capacity can be reduced by employing a two-speed motor or an electronic speed control. The electronic speed controls designed for

Figure 16-19 This control will vary the speed of a single-phase fan motor to keep the head pressure from dropping below its set point.

head pressure control work by chopping part of the sine wave out, reducing the amount of current delivered to the motor (Figure 16-19). This is the same type of control often used for ceiling fans. These controls can maintain a very steady head pressure. Speed controls should not be used with condenser fan motors that have sleeve bearings. Sleeve bearings depend on a minimum speed to maintain lubrication, and turning too slowly will grind up their bearings.

16.13 DAMPER LOW AMBIENT CONTROL

Another technique of restricting airflow across the condenser coil is the use of dampers on the fan discharge. These are used on nonoverloading centrifugal-type fans, not propeller fans. Blocking the discharge of a centrifugal fan will cause a reduction in amp draw, but blocking the discharge of a propeller fan will increase the amp draw. Dampers modulate from a head pressure controller to some minimum position, at which time the fan motor is shut off. This type of head pressure control is generally only used on larger systems.

One common and important characteristic of the airflow-restriction methods is that the full charge of refrigerant and entrained oil is in motion at all times, ensuring positive motor cooling and oil lubrication to the compressor.

16.14 FLOODED-CONDENSER LOW AMBIENT CONTROL

Condenser-flooding pressure control systems are common on commercial refrigeration systems and rare on air-conditioning systems. This is because condenser-flooding controls normally require a liquid receiver. Receivers are common in commercial refrigeration but unusual in air conditioning.

Flooding controls artificially raise the head pressure by backing the liquid refrigerant up into the condenser tubes. An “open on rise of inlet pressure” control valve, or ORI, is used to accomplish this. The ORI control is placed in the outlet of the condenser, which closes when the condenser pressure starts to drop. This restricts drainage of the liquid refrigerant out of the condenser, flooding it. The pressure in the flooded condenser increases because less condenser area is available for condensing refrigerant. When the condenser pressure is at or above the valve’s setpoint, the ORI control opens and allows liquid refrigerant to leave the condenser. Used by itself, this valve would keep the condenser pressure at the required level, but the liquid pressure after the condenser would actually drop even further when the valve is closed.

An “open on rise of differential pressure” control, or ORD, keeps the receiver pressure at the required setting. The ORD valve bypasses hot gas from the beginning of the condenser to the top of the liquid receiver. The purpose of this valve is to ensure enough pressure on the liquid receiver to keep the liquid in the liquid line at the minimum required pressure. The receiver is necessary because there must be a supply of liquid to the system while the condenser is being flooded. These two valves combined, the ORI and ORD, provide effective head pressure control under a wide range of operating conditions (Figure 16-20).

The functions of these two valves have now been incorporated into a single control, called an “open on rise of outdoor ambient,” or OROA. This single, non-adjustable control simplifies selection and application of condenser-flooding head pressure controls (Figure 16-21). However, it is available only for certain refrigerants. It floods the condenser and bypasses gas to the receiver based on the ambient temperature to maintain a minimum pressure.

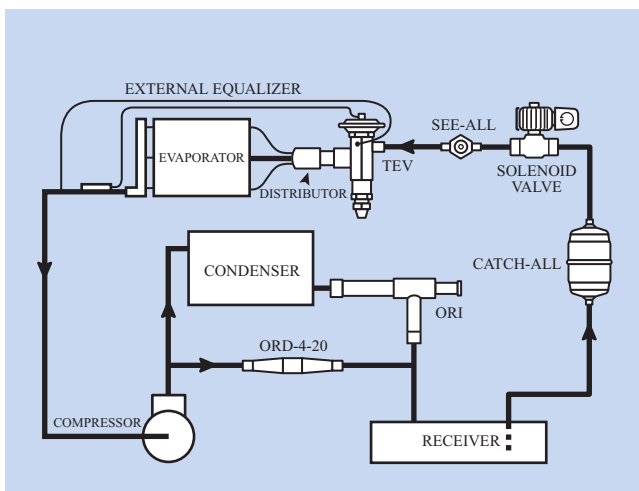

Figure 16-20 Piping diagram for application of ORI and ORD valves to control head pressure.

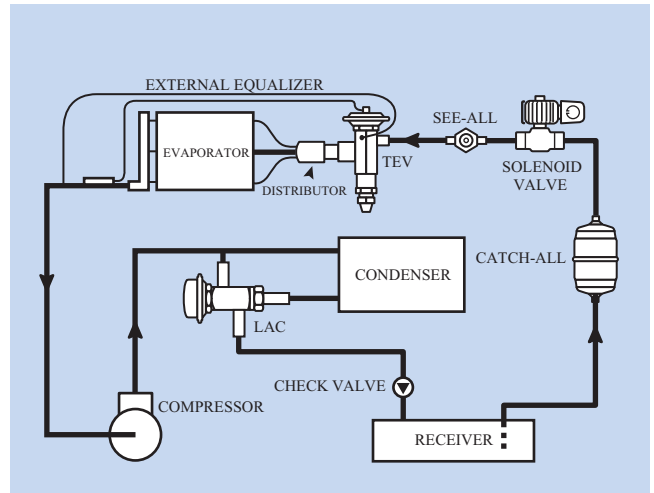

Figure 16-21 Piping diagram for application of an OROA valve to control head pressure.

Condenser-flooding head pressure controls do not suffer from pressure swings the way fan-cycling controls do, but they are more difficult to install in the field since they are piped into the refrigeration system.

TECH TIP

It is an unacceptable practice to overcharge a condenser during winter months to artificially increase the head pressure by flooding the condenser. This practice is not recommended by any manufacturer, because the first warm summer day can result in compressor failure.

16.15 SERVICING AIR-COOLED CONDENSERS

Most condenser problems are related to some type of restriction of the air. When a new condenser is installed, the operating pressures and temperature need to be recorded. These values can be referred to each time the system is serviced. A change in the observed operating conditions is a good indication that additional service work is needed.

CAUTION

If the condenser becomes dirty, its condensing pressure increases. This can be a serious problem when high-pressure refrigerants like R-410A are used. R-410A operates at normal head pressure of around 400 psig, but a dirty condenser can cause these pressures to greatly increase. Condensers are designed to withstand some amount of pressure beyond normal operating pressures. However, over time, the condenser can get progressively more dirty, resulting in elevated pressures. Catastrophic failure of the refrigerant circuit can result from excessively high pressures. It is very important that condensers containing high-pressure refrigerant, such as R-410A, be thoroughly cleaned on a regular basis.

Figure 16-22 Accumulated dirt can restrict airflow and raise the head pressure.

Accumulation of dirt on the condenser will reduce the heat transfer rate, and the compressor head pressure can rise to damaging levels (Figure 16-22). High head pressures will result in decreased system capacity, increased operating cost, and possible compressor damage. Air-cooled condenser coils will naturally collect dirt over a period of time. Annual cleaning is sufficient under normal operating conditions, but more frequent cleaning may be necessary in particularly dirty environments. Light surface accumulation can be cleaned with a stiff bristle brush and vacuum cleaner. Grease or heavy accumulations will require coil-cleaning chemicals. The equipment manufacturer should be consulted regarding acceptable cleaning products. Not all condenser coils can be chemically cleaned. Read and follow both the coil manufacturer's literature and the coil-cleaning chemical manufacturer's instructions before starting. The wrong chemical cleaner can attack the condenser and do more harm than good.

SAFETY TIP

Proper personal protection equipment should always be used when applying chemical cleaners. Typically this includes safety goggles for eye protection, gloves to protect your hands, and a long-sleeve shirt to protect your arms.

Coils may need repairing because they have been damaged mechanically or as a result of corrosion. Mechanical damage can be weather related, such as from ice and sleet, or from vandalism. Corrosion can result from environmental pollution, sprinklers, or pets.

Mechanical damage of the fins can be straightened with a fin comb (Figure 16-23). If more than 20 percent of the fins have been damaged, the condenser's efficiency will be so low that under heavy summer loads, the compressor is likely to fail. Light corrosion of the condenser fins can be removed with an approved coil cleaner. Severe corrosive damage to condenser fins may not be repairable, so the condenser coil must be replaced.

16.16 WATER-COOLED CONDENSERS

Water is a more efficient heat-transfer medium than air. The temperature difference between the refrigerant and the cooling medium is lower with a water-cooled condenser than with an air-cooled condenser. The temperature differential between the refrigerant and the leaving water is typically 10°F. Water-cooled condensers normally operate with a 15°F lower compressor discharge temperature than air-cooled units. This allows the compressor to operate at a lower discharge pressure, increasing its capacity and lowering the power requirements. This makes water-cooled units potentially more energy efficient than air-cooled units. Water-cooled condensers are also smaller and more compact than comparable air-cooled condensers.

Water-cooled systems are more expensive to install and require more maintenance than air-cooled condensers. The water must be tested and treated regularly to prevent corrosion, fouling, and scaling. While most air-cooled condensers only need an annual inspection and cleaning, the water in a water-cooled condenser may need to be checked as often as once a week, and chemical treatment is an ongoing process.

Water cooled systems require a good source of cooling water. Typical water sources include the following:

- Wastewater systems
- Open-loop cooling towers
- Closed-loop cooling towers
- Ground loops

The water can be used once and sent down the drain, or it can be recirculated. Systems that use the water only once and then put it down a drain are appropriately called wastewater systems. Water-cooled systems typically use 1.5–3 gallons of water per minute per ton. This makes wastewater systems prohibitively expensive to operate on city water for all but small systems. With water resources becoming a precious commodity in many parts of the country, wastewater systems appear to be an extravagant use of a valuable resource. Recirculating systems must find a way

to cool the water before returning it to the condenser. The most common method is to use a water tower that cools the majority of the water by evaporating a small portion of it. Cooling towers can be either open loop or closed loop. Open-loop cooling towers are called open loop because the water in the cooling tower is open to the air and the cooling tower water is the same water that circulates through the condenser. Closed-loop cooling towers use built-in heat exchangers to separate the cooling tower water from the recirculating condenser water. Another method is to use a loop of pipe buried in the ground. The water is cooled by the ground and returned to the system. These systems are called closed loops because they are not open to the atmosphere.

16.17 TYPES OF WATER-COOLED CONDENSERS

There are three basic types of water-cooled condenser construction:

- Tube in tube (coaxial)
- Shell and coil
- Shell and tube

16.18 TUBE-IN-TUBE CONDENSERS

Double-pipe condensers can be a single continuous loop, as shown in Figure 16-24, or several parallel pipes, as shown in Figure 16-25. In either case, the water and refrigerant should flow through the condenser in opposite directions. This is called counterflow. Counterflow is more efficient because the coldest water contacts the coldest refrigerant and the hottest water contacts the hottest refrigerant (Figure 16-26). Single-circuit double-pipe condensers can be constructed using a tube in tube, as shown in Figure 16-27, or two tubes soldered together and wrapped in a protective

outer tube (Figure 16-28). The tube-in-tube construction is more efficient, but cross-contamination between refrigerant and water is possible if the inside tube leaks. The tube-beside-a-tube arrangement makes cross-contamination less likely because the refrigerant and water are separated by two tube walls.

The usual arrangement for tube-in-tube coils is for a smaller tube to be placed inside a larger tube, which is sealed at the end. Water travels through the smaller tube and refrigerant travels through the larger tube.

When multiple tubes are used, they connect to the headers. The water flows through the inner tube and the refrigerant flows through the angular space between the tubes. The inner tube may have a spiral surface (Figure 16-29). This agitates the water as it flows through the tube so that it does not stratify with the cooler water flowing in the center of the tube. An advantage of this design is that it can be wrapped into a shape to fit the space available. For example, the packaged condensing unit shown in Figure 16-30 uses the tube-in-tube condenser.

Figure 16-29 The twisted tubing shape improves heat transfer by creating turbulence in the water.

Figure 16-30 Typical use of a tube-in-tube condenser designed for in-the-room installation.

Single-circuit tube-in-tube condensers are used on most water-source heat pumps. They are generally not accessible and can only be cleaned and descaled chemically. Parallel-circuit condensers with headers can usually be mechanically cleaned by removing the header access plates on each end.

The water tubes of a double-pipe condenser are typically made of copper, while the refrigerant pipe is made of copper or steel. The pipes can be constructed of stainless steel or cupronickel if more resistance to corrosion is required. Cupronickel coils are made of an alloy of 90 percent copper and 10 percent nickel that is more resistant to corrosion than copper.

CAUTION

Care is required when recovering refrigerant from a water-cooled condenser. During the recovery process, liquid refrigerant in the water-cooled condenser can vaporize and draw the temperature down to below the freezing temperature of water. Ice formed inside any sealed container such as a water-cooled condenser can rupture the vessel or damage the internal piping. To avoid this, liquid refrigerant should be recovered first to avoid boiling the refrigerant at a low pressure and temperature. The water must either be continuously circulated or else completely drained before recovering the refrigerant.

16.19 SHELL-AND-COIL CONDENSERS

Shell-and-coil condensers are typically used in larger systems. Shell-and-coil condensers are constructed with a welded steel shell and an internal finned copper tubing coil. Water flows through the finned coil, and the refrigerant in the shell condenses on the coil. The shell can run vertically for better heat transfer through convection or horizontally to meet possible space requirements. Shell-and-coil condensers also act like liquid receivers.

In a vertical shell-and-coil condenser, the water enters at the bottom of the coil and travels up. The refrigerant enters at the top of the shell, condenses, and leaves at the bottom of the shell.

Shell-and-coil condensers are sometimes used with water-source heat pumps and can be combined with the compressor to form a condensing unit package. These units are usually limited to 20 tons or less. Vertical-packaged air-conditioning units from 20 to 60 tons use shell-and-coil condensers due to their compact dimensions.

Shell-and-coil condensers are difficult to service in the field because of their construction and cannot be cleaned mechanically. They can only be cleaned and descaled chemically.

16.20 SHELL-AND-TUBE CONDENSER

The shell-and-tube type condenser (Figure 16-31), is used in the largest condensers. Capacities extend to 1,000 tons. Water flows through the tubes (the tube side of the condenser), and refrigerant flows on the outside of the tubes (the shell side of the condenser). These condensers have long, straight finned tubes, connected to a steel plate (tube sheet) at each end. At each end, water manifolds, called heads, are bolted to the shell (Figure 16-32). These heads direct the water to make from one to eight passes, depending on the size and design of the condenser. The heads can be removed to permit cleaning the individual tubes. Rubber gaskets provide a watertight seal.

The entering water in recirculated systems is typically warmer than with wastewater systems. Single pass and double pass designs are used for water tower systems to

Figure 16-32 Shell-and-tube condenser header configuration. (Image Courtesy of Alfa Laval)

keep the difference between the condenser saturation and incoming water temperatures as low as possible, improving the efficiency of the refrigeration system. A higher water flow rate is required with fewer water passes because the condenser is operating at a lower water temperature rise. Multiple-pass designs are used to minimize water use by increasing the amount of heat picked up by each pound of water. Multiple-pass configurations operate with a higher temperature difference between the condenser saturation and incoming water temperatures and are used when water is scarce or expensive, such as for city wastewater systems (Figure 16-33).

In a typical water condenser, the hot gas inlet and purge valve are on the top, the liquid outlet valve is on the bottom, and the pressure-relief valve is on the side. Many of these shell-and-tube condensers are used in large, water-cooled condensing units ranging in size from 5 to 150 tons. A common use of the shell-and-tube condenser is as a component of a water chiller, as shown in Figure 16-34.

16.21 WASTEWATER SYSTEMS

In earlier applications of water-cooled condensers to refrigeration and air conditioning, it was common practice to tap the water supply and then waste the discharge water to a drain connection as shown in Figure 16-35. An adjustable automatic water-regulating valve was placed in the line of the flow of incoming water to control the condenser operating head pressure and temperature. It got the system pressure through a pressure tap.

The temperature of the incoming water would naturally affect the condenser performance and flow rate of any heat load. Depending on the geographic location, water temperatures in city water mains rarely rise above 60°F in summer and frequently drop to much lower temperatures in winter.

Condensers piped for tap water flow were always arranged for series flow and circuited for several water passes to achieve maximum heat rejection to the water, which was then wasted (see Figure 16-33). Condensers drawing on city water used only 1 to 1½ gpm (gallons per minute) per ton of refrigeration. The multipass circuit created high water pressure drops ($P_1 - P_2$) of 20 psi or more; however, most

city pressures were able to supply the minimum pressure requirement (usually 25 psig).

Because of water shortages experienced in many areas of the country, water-cooled condensers that waste water are not recommended. The cost and scarcity of water (unless drawn from a lake or wells and returned) has become prohibitive and is even outlawed for refrigeration and air-conditioning use by many local city codes. Ordinances have restricted the use of water to the point where such installations have been forced to use all air-cooled equipment. Some water regulations are so restrictive that they may even require existing wastewater-cooled systems to be replaced. Most system operators have switched to water-saving devices such as the evaporative condenser or water tower.

Residential Well Systems

Many residential water-cooled systems have been installed as wastewater systems on private wells. Even well water is not free, because energy is required to pump the water. Operating a ½-hp water pump to move the water from the well to the unit can be a significant additional operating expense. Wastewater systems are more prone to mineral scaling than other types of water-cooled systems because the continual supply of fresh water also provides a continual supply of fresh minerals. The condenser efficiency drops off as scale builds inside it, insulating the tube walls from the water.

The head pressure of a water-cooled system is affected by the inlet water temperature. Wastewater systems use a water-regulating valve to control head pressure by adjusting the water flow through the condenser. The water-regulating valve measures the head pressure, increases the water flow when the head pressure increases, and decreases the water flow when the head pressure decreases.

16.22 COOLING-TOWER SYSTEMS

In most installations using water-cooled condensers, water is supplied to the condenser from a cooling tower. The heated water from the condenser is returned to the tower to dissipate the heat picked up from the refrigerant, as shown in Figure 16-36). There are four steps in the process:

- Heat is transferred from the refrigerant to the water in the condenser.
- The water is pumped from the indoor condenser to the cooling tower outdoors.
- At the tower, the heat is rejected to the outdoor air, cooling the water.
- The cooled water is returned to the condenser to pick up more heat, making a continuous process.

Typical operating conditions for a water tower system are as follows:

- The refrigerant condensing temperature is about 105°F.
- The water entering the condenser is approximately 85°, which is 20°F lower than the condensing temperature.
- The water temperature rises about 10°F in passing through the condenser, leaving the condenser at about 95°F.
- The leaving water is only 10°F below the saturated refrigerant temperature.

When the water gets to the cooling tower, it is at 95°F. The warm water drops over the cooling tower's wetted decking, while outside air moves past it in the opposite direction, causing evaporation. Each pound of water that is evaporated removes 970 BTU from the remaining water, cooling it. A 10°F drop in temperature occurs by the time the water reaches the bottom of the tower. This 85°F water is returned to the condenser to absorb more heat. Water is lost by evaporation, drift, and blowdown. Drift is atomized water that has not vaporized but is caught by airstreams and carried away. Blowdown is the periodic intentional re-

lease of water to reduce the mineral concentration in the water. This water is replaced by makeup water, which is regulated by a float valve in the sump of the tower. See Unit 82, Cooling Towers, for more information on cooling-tower systems.

TECH TIP

Water-cooled condensers are more efficient than air-cooled condensers. This does not mean that a homeowner should put a sprinkler on an air-cooled condenser to increase its efficiency. Continuous watering of an air-cooled condenser coil will result in mineral buildup on the coil, which will ultimately reduce the coil's efficiency. In addition, many minerals are corrosive to the fin material, so that over time the aluminum fins will be corroded away.

16.23 CONDENSER WATER TREATMENT

When a water-cooled condenser is used, a constant supply of water is needed. If the water is being recirculated through a cooling tower, it must be treated to prevent corrosion, scaling, and the formation of algae. If the water treatment is not maintained, the tower will become fouled and stop working. Regular testing of the condenser water is the key to maintaining a healthy water-cooled system. Three different aspects of water conditioning must be monitored:

- Water pH
- Mineral content
- Biological growth

Water pH Control

The pH scale is a measure of the concentration of hydrogen ions in solution. It runs from 0 to 14. Lower numbers represent acidic conditions, and higher numbers represent alkaline conditions. A neutral solution is 7 on the pH scale. Typically, cooling tower water is maintained at a pH between 6.5 and 9. The circulating water can become corrosive if it is too acidic. A pH lower than 6 will aggressively attack metal surfaces, and high pH will encourage mineral deposits. Biological growth tends to raise the water pH level, leading to scaling. Most tower water will be alkaline, high pH, if left alone. Small amounts of acid are added to keep the pH down.

Scaling

Scaling occurs when minerals dissolved in the water precipitate out on the condenser and cooling-tower surfaces (Figure 16-37). The hard scale deposits act like insulation. Heat-exchange surfaces that have $\frac{1}{16}$ in. of scale have a 50 percent reduction in capacity. Scaling can be controlled by pH control, the addition of inhibitors that discourage mineral precipitation, and with water bleed-off.

The concentration of minerals in the cooling tower increases as the tower is operated. When water evaporates it leaves its mineral behind, effectively increasing

Figure 16-37 Scale deposits on cooling-tower components reduce the tower's cooling capacity. (Courtesy of ChemFresh)

the mineral concentration of the remaining water. A small amount of water is intentionally drained off of the bottom of the cooling tower sump to keep mineral concentration under control. The high-mineral-concentration water is replaced with relatively low-mineral-concentration water, reducing the overall mineral concentration in the sump.

Biological Fouling

Biocides are added to the water to prevent growth of organisms in the cooling-tower water. Water is a fundamental requirement for life. Leave some water sitting around in the open, and soon it will be teeming with life. The warm, untreated cooling-tower water becomes a petri dish, and an impressive array of bio-organisms springs forth, including bacteria, fungi, algae, and even protozoa organisms. As the organisms flourish, they attach themselves to all the tower surfaces, creating a coating called a biofilm. A well-established biofilm can be difficult to remove. Biological fouling is considered by many to be the root of most cooling-loop water-treatment problems. Problems created by biological fouling include reduction in heat-transfer efficiency, clogged cooling-tower fill, water-flow blockages, corrosion, and hazards to human health, like *Legionella*.

SAFETY TIP

Legionella was discovered because of an outbreak in 1976 at an American Legion convention, where 221 people became ill and 34 people died. Investigation revealed *Legionella* was growing in cooling-tower water and was spread through the mist created by the cooling tower. Failure to control its growth can lead to illness and death of people who come in contact with the spray from the tower.

Water Control in Open Systems

Water treatment is very different in open systems and closed systems. Open systems are exposed to more potential contaminants. Typically chemicals are added to main-

tain the proper pH, to inhibit scale formation, and to act as a biocide. Chemical treatment is usually done continuously using automatic chemical feed devices. Even with an automated system, the water should be tested and monitored on a weekly basis. The types and amount of chemicals used may need to be adjusted as conditions change.

Water Control in Closed Systems

Water control is easier in closed systems because the water is not exposed to the atmosphere, and makeup water is not continuously bringing in new minerals. A single chemical charge is usually sufficient when the loop is filled. The water should be tested quarterly because the water conditions will change over time, even in a closed system.

16.28 EVAPORATIVE CONDENSERS

Evaporative condensers are similar to closed-loop cooling towers, except the coil is a refrigeration coil instead of a water coil. They work by evaporating water to cool the refrigeration coil. Hot refrigerant vapor travels through the inside of the copper coil as cold water is sprayed over the exterior of the coil. Fresh air is pulled up over the exterior of the coil while cold water is sprayed down over the coil. Heat from the refrigerant is transferred to the spray water, causing the refrigerant to condense from a gas to a liquid. Heat from the spray water is discharged to the atmosphere through evaporation of the spray water. Evaporative condensers provide lower condensing temperatures and can offer significant horsepower savings over conventional air-cooled and water-cooled condensing systems.

The condensing coil rejects heat through both evaporative cooling using the fresh airstream and through sensible cooling using the precooled recirculating spray water. The recirculating spray water falls from the coil to a fill surface section, where it is cooled by a second fresh airstream using both evaporative and sensible heat-transfer processes. The cooled water increases the temperature differential between the water and the refrigerant. This cool water is then pumped back up to the spray heads to absorb more heat from the condenser.

16.29 CONTROLLING EVAPORATIVE CONDENSER CAPACITY

There are a number of arrangements for controlling the capacity of evaporative condensers:

- Shut off the water sprays. This reduces the evaporative condenser to an air-cooled condenser. The air-cooled capacity is 50–60 percent of the wetted capacity. This, however, is a huge step in capacity reduction. Shutting off the water may increase scaling.
- The fan can be cycled. This can shorten the belt life.
- Modulate the fan speed. This method gives better control with less likelihood of increased scaling.
- The airflow through the condenser can be controlled using dampers.

Figure 16-38 Three ways to control the airflow on the evaporative condenser.

Airflow can be controlled using dampers in the outlet of the blower, in the outlet of the tower, or in a bypass duct. Warm humid air from the condenser discharge can be mixed with outdoor air by the use of bypass dampers and ductwork. This increases the relative humidity of the air entering the unit, reducing evaporation and, therefore, reducing the condenser capacity. Figure 16-38 shows three ways to control the capacity of an evaporative condenser by controlling the airflow.

16.30 SERVICING WATER-COOLED CONDENSERS

The first step in servicing water-cooled equipment is to check the water flow. All other checks on a water-cooled system are useless if the water flow and temperature are not right! The water flow rate can be checked by checking the pressure drop through the unit and comparing it to the manufacturer's specifications. Some systems have water

Figure 16-39 Fouled condenser. (Courtesy of www.tubetech.com)

flow indicators that make checking the water flow as easy as looking at a gauge. Check the water flow against the manufacturer's specifications. If the system has a log book, check the data in the log book and compare the current water flow against the baseline. Once the water flow is correct you can proceed to check the other system operating characteristics.

Fouled Condenser

Fouled condensers are the most common problem with water-cooled equipment (Figure 16-39). A fouled condenser is indicated by a higher than normal discharge pressure and a higher than normal temperature difference between the condenser saturation temperature and the leaving water temperature. In cooling tower systems, the normal temperature difference between the condenser saturation temperature and the leaving water temperature is 10°F. Wastewater systems commonly operate at a slightly higher temperature difference of 15°F. Fouled condensers do not dissipate heat as well, so the condenser temperature rises. The water pressure drop across the condenser will also increase because the condenser tubing will be effectively smaller. On wastewater systems with water-pressure-regulating valves, more water will be flowing than normal as the valve attempts to compensate for the high head pressure. The combination of increased water flow and poor heat exchange will cause the temperature difference across the condenser to decrease. The normal temperature difference across the condenser on cooling-tower systems is 10°F. Wastewater systems using city water can vary widely because of large temperature differences in the incoming water.

Low Water Flow

Reduced condenser water flow will cause an increase in head pressure and increase the temperature difference across the condenser. The temperature difference between the condenser saturation temperature and the leaving water temperature will remain about the same. Low water flow is often caused by fouled water-handling components. Plugged pump inlet screens or scaled water pipes can reduce the amount of water the pump can deliver.

Cleaning and Descaling

All water-cooled condensers lose efficiency over time as the result of internal water-tubing fouling. Proper water maintenance will greatly reduce the amount of condenser maintenance required. Large tube-and-shell condensers may be mechanically cleaned by draining the water, removing the access plates, and running brushes or rods through the water tubes (Figure 16-40). This is typically done annually. Coaxial and shell-and-coil condensers can only be cleaned chemically by circulating a cleaning chemical agent to dissolve scale and oxides. The water system should be drained and flushed following a chemical cleaning. Follow the manufacturer's cleaning instructions, and read and follow all of the cleaning chemicals' safety instructions.

16.31 HEAT RECLAIMING

All refrigeration and air-conditioning systems produce waste heat when they are making something cool. That heat from either cooling process is by definition being moved from a place where it is not wanted to a place where it does not matter. Heat reclaiming is a process that makes use of the waste heat from a cooling process by moving it to a place where it is wanted.

Figure 16-41 This unit has a heat exchanger built into it for heating domestic hot water.

Everyone needs some hot water even on the hottest day in the summer. Too often we use expensive energy sources like natural gas or electricity to produce that hot water. On the coldest day of the winter, restaurants, supermarkets, schools, and hospitals have something they are keeping cold in a walk-in freezer or refrigerator.

A desuperheating coil added to the hot gas line of any air conditioner or refrigeration unit can produce the heat to make hot water. The waste heat from these cooling systems is always free and in some cases can reduce the high-side pressure and temperature on the condenser to save even more money. Desuperheaters can be added to existing systems or built into the system at the factory (Figure 16-41).

CAUTION

Desuperheaters must have thermostats and safety switches to protect the water heater from being overheated. Desuperheaters may even boil the water in the heater without these controls.

The core of a large building often does not need heat even on cold winter days. The heat from lights, equipment, and people is often more than is needed to keep this area warm. In fact, sometimes some mechanical cooling is required on all but the coldest days. The waste heat from this core cooling can be redirected to the perimeter of the building, which probably needs some heat on these cold days.

Waste building heat can be recycled through the building's forced-air or hydronic system. Forced-air systems are the easiest to set up to use waste heat. In most cases, all that is needed is to add a condenser coil in the supply or return air ducts. For a hydronic system, the heat can be collected with a desuperheater to be added to the hydronic heating system.

Some supermarkets use heat-reclaiming condensers to capture the heat from operating their refrigerated cases in the winter. The refrigerated cases operate year round, but the supermarket typically needs heat in the winter. The discharge gas from the compressor is directed to a condenser in the store's duct system, where it can be used to heat the store.

UNIT 16—SUMMARY

The job of the condenser is to reject heat from the refrigerant by condensing a hot refrigerant vapor to a warm liquid. The refrigerant is desuperheated, then condensed to a liquid, and finally the liquid is subcooled. Approximately 80 percent of the heat removal occurs because of the condensing process.

WORK ORDERS

Service Ticket 1601

Customer Complaint: Poor Cooling and High Power Bills

Equipment Type: R-22 Split-System Air Conditioner with an Air-Cooled Condenser

The customer lives on a heavily traveled dirt road. He complains that the system runs more than it did when it was new and does not seem to cool as well. He also notes that his power bill is considerably higher than when the system was first installed. He asks the technician to add some refrigerant to make the system cool better. The technician notes that the system is five years old and has never been serviced. The technician shows the customer that the high-side pressure is 325 psig, almost 100 psi higher than the pressure specified on the system charging chart located on the inside panel of the equipment. The technician explains that adding refrigerant would only make matters worse and shows the customer the dirt caked on the condenser. The customer agrees to have the condenser cleaned. After cleaning, the system operating pressures return to normal, the compressor cools off, and the unit amp draw decreases.

Service Ticket 1602

Customer Complaint: System Not Operating

Equipment Type: R-22 Split-System Air Conditioner with an Air-Cooled Condenser

A customer complains that her one-year-old system is not operating. The customer is especially upset that she paid to have the system recharged just last month. The technician sees a large white area on the condenser fins and uses a volt meter to determine that the low-pressure switch is open and preventing the system from operating. A pressure check reveals that there is no refrigerant in

the system at all. A large, overly friendly dog approaches, slobbers on the technician, lifts his leg, and wets the condenser coil. The technician adds a nitrogen charge to look for leaks and hears a hissing sound from the white area of the condenser. The technician informs the customer that the condensing coil leaks because of corrosion due to the acidic nature of the dog urine and recommends replacing the condenser and moving the dog to an area away from the condenser.

Service Ticket 1603

Customer Complaint: High Process Water Temperature

Equipment Type: Process Water Chiller Connected to Open Water Tower

A manufacturing company uses a water chiller to cool the water used to cool the machines in their plant. The company has noticed that the chiller is unable to maintain the desired process water temperature. The technician notes that the temperature of the water entering the condenser is 100°F and appears to be climbing. The temperature leaving the condenser is 106°, only 6°F warmer than the entering temperature, indicating reduced system capacity. The condenser saturation temperature is 120°F. The water in the cooling tower appears murky, and parts of the tower are heavily coated with scale. The technician shows the plant manager the cooling tower and recommends a thorough cleaning of the tower and condenser, followed by a routine water-treatment regimen to prevent the problem from recurring. The plant manager agrees to the cleaning but defers the decision on water treatment to the home office, noting that they had discontinued regular water-treatment service about a year ago to reduce operating cost. The technician points out that the increased electrical use due to inefficient operation probably exceeded the cost of regular maintenance, so neglecting maintenance effectively increased operating cost.

Customer Complaint: System Cuts Off Periodically

Equipment Type: R-22 Water-Source Heat Pump Unit with a Tube-in-Tube Condenser on a Wastewater Well System

A customer complains that his ten-year-old water-source heat pump periodically shuts itself off. He has figured out that if he pushes a red button marked RESET, the system will often start and run for a while before stopping again. The button is a manual reset high-pressure switch. The technician measures the system operating pressures and temperatures. The high-side pressure starts high and continually rises until it reaches 375 psig, when the technician shuts the system down. The pressure drop across the coil is higher than normal, and the temperature rise in the condenser water is only 5°F. The leaving

water temperature is 90°F. The technician informs the customer that his water coil is fouled, causing high head pressure, which trips the high-pressure switch. The technician recommends either replacing the coil or the entire unit because this type of coil cannot be mechanically cleaned.

Metering Devices

OBJECTIVES

After completing this unit, you will be able to:

1. list the different types of metering devices.
2. explain the difference in operation between fixed and modulating metering devices.
3. describe how to measure superheat.
4. explain the purpose of liquid distributors.
5. explain the difference in operation between conventional and balanced-port expansion valves.
6. discuss common metering device problems.

17.1 INTRODUCTION

A metering device controls the flow of refrigerant to the evaporator. It separates the high-pressure side from the low-pressure side. The evaporator pressure is low because the compressor is continuously pumping vapor from the evaporator while the metering device is restricting the flow of refrigerant into the evaporator. Refrigerant enters the metering device as a subcooled liquid and leaves it as a saturated mixture that is approximately 75 percent liquid and 25 percent vapor. The pressure and temperature at the outlet of the metering device correspond to the saturated condition required to establish the desired evaporator temperature.

17.2 TYPES OF METERING DEVICES

Metering devices are selected by application. They can be generally classified by operation as belonging to one of two groups: fixed metering devices and modulating metering devices. Fixed metering devices are simpler and less expensive than modulating metering devices. They are basically an engineered hole, designed for a specific set of operating conditions. The capillary tube and the orifice (piston) are examples of fixed-type metering devices.

Modulating metering devices have the ability to respond to changes in system operation. This allows modulating-type metering devices to be used on a wider range of applications. Modulating metering devices will usually operate more efficiently than fixed metering devices, especially if the refrigeration load conditions vary. The low-side float, high-side float, automatic expansion valve, thermostatic expansion valve (TEV), and electronic expansion valve are examples of modulating metering devices.

to be monitored and adjusted by hand to match the load. These valves were used in the past on applications where the load was fairly constant and an operator was present to manually make adjustments when necessary. The hand expansion valve was often used on ammonia systems that had a nearly constant load and where an operator was available to make adjustments when needed. It is seldom used today, except in laboratory tests to explore optimum flow rates.

17.3 METERING DEVICE OPERATION

A metering device is a type of restrictor placed in the liquid line between the condenser and the evaporator to produce a difference in pressure between the high side and the low side of a refrigeration system by regulating the flow of refrigerant. The amount of the restriction must balance the work of the compressor to maintain the correct condensing and evaporating temperatures.

The temperature of the warm refrigerant liquid must be reduced before it can absorb heat in the evaporator. The pressure of the refrigerant is reduced as it flows through the metering device. The drop in pressure causes a small portion of the liquid refrigerant to vaporize, cooling the remaining liquid.

Refrigerant that evaporates as the result of a pressure drop is called flash gas because the liquid turns to vapor instantly, "in a flash" (Figure 17-1). Heat is required

Figure 17-1 How flash gas is formed when the liquid refrigerant flows through the metering device.

TECH TIP

A type of metering device that is seldom used today is the hand-operated expansion valve. It is a fixed valve whose capacity is adjusted by hand. The obvious disadvantage of the hand expansion valve is that it has

to make the liquid refrigerant boil. Since no heat is being added, the heat must come from the remaining liquid refrigerant. The flashing refrigerant absorbs heat from the remaining liquid refrigerant, reducing the temperature of the remaining liquid. Between 25 and 30 percent of the liquid typically flashes to vapor as the refrigerant flows through the metering device. Expansion that occurs without adding any heat from outside the process is called adiabatic expansion.

Referring to Figure 17-2, the volume of the refrigerant increases from around 28 in³/lb entering to approximately 268 in³/lb leaving. This expansion creates a large pressure drop from 418 psig to 118 psig. The pressure drop causes a corresponding temperature drop from 105°F to 40°F. The specific enthalpy is unchanged because the heat required to vaporize the flash gas came from the remaining liquid.

17.4 METERING DEVICE LOCATION

The metering device is located between the condenser and the evaporator. Typically the metering device is actually connected to the evaporator. The metering device is supplied with most air-conditioning evaporator coils. Air-conditioning evaporators are typically manufactured with the metering device as an integral component (Figure 17-3). Ductless mini-split systems are a notable exception. Many of these systems have the metering device located in the outdoor condensing unit (Figure 17-4). The liquid line on these systems must be insulated because they carry cold, saturated liquid rather than a warm, subcooled liquid. The metering device is more commonly field installed in commercial refrigeration. It is still attached to the evaporator, but the installation technician must install it in the field (Figure 17-5).

17.5 FIXED METERING DEVICES

There are two types of fixed metering devices: the capillary tube and the fixed orifice (Figure 17-6). Fixed-restriction metering devices operate best where the load is nearly constant. Their operating principle is simple: when a pressurized fluid passes through a small hole, the resistance to flow through the hole causes a drop in pressure. While the operating concept is simple, the design and application of

Figure 17-3 The metering device comes installed as part of an air conditioning evaporator.

fixed-restriction metering devices is anything but simple. Since a fixed hole cannot adjust itself to pressure changes, improper sizing can easily lead to flooding or starving the evaporator, both of which may be harmful to the compressor. The size of that opening and the amount of charge are critical to correct operation.

Many technicians expect a fixed amount of refrigerant to pass through a fixed metering device since the device cannot adjust. However, changes in pressure difference across a fixed metering device will cause changes in flow precisely because the device cannot adjust. The reason refrigerant goes through a restriction at all is because of a difference in pressure across it. Both the low- and high-side pressures tend to be influenced by factors, such as the outdoor

Figure 17-4 The metering device on this mini-split system is located in the outside unit.

Figure 17-5 Commercial refrigeration evaporators typically do not come with a metering device already installed; this expansion valve was installed in the field.

Figure 17-6 The capillary tube on the left and the orifice on the right are the primary types of fixed-restriction metering devices.

temperature, that are beyond the control of the machine. In an air-conditioning system, the head pressure increases as the outdoor temperature rises. This increase in head pressure causes an increase in the pressure difference across the orifice. As the pressure difference across the restriction increases, more refrigerant will go through it. This increased flow will cause a rise in suction pressure, but the suction pressure will not increase quite as much as the head pressure that caused the increased flow. The increased flow will also have the effect of reducing superheat, since more refrigerant is now being delivered to the evaporator. A check of the compressor motor amperage will reveal a relatively higher current draw from an increased system load.

Lower outdoor ambient temperatures will produce lower head pressures, reducing the pressure drop across the fixed restriction. This reduced pressure difference will result in reduced refrigerant flow to the evaporator. Decreased flow will cause a drop in suction pressure and an increase in superheat, since less refrigerant is now being delivered to the evaporator. A check of the compressor motor amperage will reveal a decrease in the system load. Figure 17-7 shows the operating characteristics of an air conditioner with a fixed restriction at different outdoor ambient temperatures.

Changes in temperature at the evaporator have an opposite effect from changes in condenser temperature. An increase in temperature at the evaporator causes an increase in evaporator pressure. This has the effect of reducing the pressure difference across the metering device, which reduces the refrigerant flow to the evaporator and raises the superheat. Decreased temperature at the evaporator decreases the evaporator pressure, increasing the refrigerant flow through the metering device and decreasing the superheat. Figure 17-7 shows the effect of indoor wet bulb temperature on system operation.

Because the flow through a fixed restriction changes depending upon the operating conditions, the only time a system with a fixed metering device produces its full capacity is at design conditions. The AHRI standard design conditions for air conditioning are 95°F outdoor ambient temperature, 80°F indoor dry bulb temperature, and 67°F indoor wet bulb temperature. A 24,000 BTU, AHRI-rated air conditioner with a fixed expansion device will not produce 24,000 BTU worth of cooling at an outdoor ambient of 75°F.

This change in capacity shows up in the system superheat. Most manufacturers using orifices or capillary tubes publish superheat charts that specify what the system superheat should be at any operating condition that falls within the operating range of the unit. A look at one of these charts will show that as the outdoor ambient temperature goes up, the system superheat goes down; and conversely, as outdoor ambient temperature goes down, the system superheat goes up. In fact, most air conditioners with fixed-restriction metering devices are operating under starving conditions at ambient temperatures less than 95°F. An orifice-equipped unit can have a superheat as high as 45°F at its lowest operating limit. This superheat is what determines the system's lowest operating temperature limit. The compressor on a system using a fixed restriction can overheat due to lack of cooling for the compressor motor when operating at low ambient conditions. That's correct: low ambient operation can cause overheated compressors!

Figure 17-7 Operational characteristics of R-410a air conditioner with fixed restriction.

Adding charge at the low ambient condition will produce a more fully active evaporator and reduce the superheat, but then the system will flood back at higher ambient temperatures when the superheat naturally drops.

A characteristic of systems using fixed-restriction metering devices is that the system high-side and the low-side pressures equalize when the compressor shuts off. Since the metering device is simply a hole, refrigerant will continue to flow through it until the pressures on both sides of it are the same. This can be an advantage in system design because the compressor does not have to start against a pressure differential. This permits the use of a low starting torque compressor motor. This can also be a disadvantage, since the evaporator can be filled with liquid on shutdown. On the next startup, the liquid can flood back to the compressor and cause damage. System equalization also encourages refrigerant migration to the compressor

crankcase. When the system starts, the oil and refrigerant mixture foams violently, reducing lubrication. Neither of these problems is pronounced on small systems with limited charge, but they can become serious on larger systems. Crankcase heaters and suction line accumulators can be employed to mitigate these problems on larger systems.

Systems using fixed-restriction metering devices do not use liquid receivers. Without a receiver, if refrigerant is condensing faster than it is flowing through the metering device, liquid starts to pile up in the bottom of the condenser. This raises the head pressure and helps force more refrigerant through the metering device. Any refrigerant storage must be accomplished on the low side of the system with a suction accumulator.

Systems can counteract the problem of refrigerant floodback by using a suction line accumulator at the entrance to the compressor, as shown in Figure 17-8. This

Figure 17-8 A suction line accumulator can trap liquid refrigerant before it reaches the compressor.

captures the liquid refrigerant and returns it to the system as vapor. Because liquid refrigerant is evaporated from an accumulator, these devices get very cold and often sweat. This condensation can cause accumulators to rust over time, as in Figure 17-9. On older units, the rust can weaken the accumulator to the point where it can fail.

SERVICE TIP

It is easy to overcharge an air-conditioning system with a fixed restriction in mild weather. For example, suppose a technician is checking an air conditioner on a 75°F day. The unit operates with a moderately high superheat of 30°F. The suction line feels cool, but not really cold. Since the evaporator is obviously starved, the technician adds refrigerant until the suction line is cold and the superheat is 10°F. The unit begins cooling a little better. The customer is happy until the temperature climbs to 95°F outside. As the outdoor temperature rises, the superheat drops. Since the unit has been charged to operate at a low superheat under a 75°F ambient, the evaporator will flood at a 95° ambient. The flooded evaporator does not cool as well as it should, so the capacity of the unit is reduced just when it is needed the most. Since the unit is operating at reduced capacity and increased pressure, it uses more electricity, costing the customer more money. Because the evaporator is flooded, liquid will be returned to the compressor and damage it, further reducing the capacity of the system. The moral: air-conditioning systems with fixed-restriction metering devices should operate at relatively high superheats in moderate weather. Do not overcharge them.

17.6 CAPILLARY TUBES

The capillary tube is probably the simplest of all metering devices. It is constructed of a seamless copper tube with an inside diameter ranging in size from 0.026 in to 0.090 in

Figure 17-9 Rust formed on the accumulator due to condensation.

(Figure 17-10). Capillary tubes may be found on older models of central air conditioners but are seldom used today in residential air-conditioning systems. Capillary tubes are still commonly used as a metering device on domestic refrigerators, window units, and other small appliances. In these appliances, the capillary tube doubles as a metering device and the liquid line; the refrigerant travels from the condenser to the evaporator through the capillary tube (Figure 17-11). Capillary tubes are frequently longer than the distance they must travel and are sometimes coiled to conserve space, as in Figure 17-12.

Small systems like refrigerators typically use a single capillary tube for their metering device. The evaporator coil on these systems is a single circuit coil: refrigerant enters at the start of the coil and exits at the end of the coil. Larger units using capillary tubes may use multiple capillary tubes feeding multicircuit coils. A multicircuit coil has several entry points and exits. Essentially, a multicircuit coil is like several small coils manufactured together. Each circuit has its own capillary tube (Figure 17-13). Systems with multiple capillary tubes use a small distributor tube to feed all of them (Figure 17-14).

The size and the length of the tube are carefully selected to match the pumping capacity of the compressor at full load. Capillary tubes depend on their length as well as their diameter to determine their total restriction. Increasing the diameter or decreasing the length of the capillary tube decreases the pressure drop through it, increasing its capacity. Decreasing the diameter or increasing the length of the capillary tube increases the pressure drop through it and decreases its capacity. The pressure of the liquid refrigerant passing through the capillary tube drops slowly in the first 25 percent of the capillary tube length. When the pressure has dropped to the saturation pressure for the refrigerant temperature, the liquid starts to flash. The flash gas causes

Figure 17-10 Typical capillary-tube metering device.

Figure 17-11 The capillary tube in a window unit runs from the outlet of the condenser to the inlet of the evaporator.

Figure 17-12 The capillary tube is coiled when it is longer than the distance it must travel.

Figure 17-13 The coil has four circuits, each fed by its own capillary tube.

Figure 17-14 The four capillary tubes for this multicircuit coil are fed by a capillary-tube distributor.

a rapid drop in pressure starting at that point. This point on the capillary tube can be felt. The first part is still warm to the touch; the part containing flash gas is cool to the touch.

Systems using capillary-tube metering devices have no provision for refrigerant storage. The charge in these systems is critical because the capillary tube cannot adjust, the systems have no provision for refrigerant storage, and a small change in charge can have a large impact on system pressures. Most systems that use a capillary tube as their metering device are packaged units such as domestic refrigerators, freezers, and window air conditioners. These systems are evacuated and charged at the factory.

17.7 INSTALLING CAPILLARY TUBES

Capillary tubes are not generally field-selected components. However, capillary tubes may occasionally need replacing. The best sizing procedure is to replace the capillary tube with exactly the same size and length. Even the coiling makes a difference. Many manufacturers sell replacement capillary tubes that are the exact replacement, including the shaping of the capillary tube. If a capillary tube must be cut during installation, it should be cut with a small triangle file (Figure 17-15). File a groove all the way around the tube and then bend the tube back and forth until it breaks at that point without creating a burr. Capillary tubes are too small for most tubing cutters. Even if a tubing cutter manages to cut a capillary tube, it leaves a large burr, which adds additional restriction. This additional restriction will create an excessive pressure drop. Wire-cutting pliers will actually pinch the tubing shut. Figure 17-16 compares a capillary tube that has been cut using wire pliers with a capillary

tube that has been cut with a small file. When installing a capillary tube, it should be inserted at least an inch past the point it enters to prevent brazing material from plugging its end (Figure 17-17).

Due to the small size of the tube, it can be easily plugged. Metal shavings, dirt, moisture, filings, flux, or oxides from brazing can all enter the system during manufacture and installation. Every precaution should be taken to keep these contaminants from entering the system during the installation process. Many systems use a built-in liquid line filter at the entrance of the tube (Figure 17-18).

Figure 17-18 This filter prevents debris from clogging the capillary tube.

17.8 TROUBLESHOOTING CAPILLARY TUBES

A restricted capillary tube is the primary problem encountered on capillary-tube metering devices. A restricted capillary tube will operate with a low suction pressure, a high superheat, and a high subcooling. The solution depends upon the reason for the restriction. The restriction can be from solid debris like copper shavings and copper oxide scale, or it can be from water. If the capillary tube is plugged with solid debris, it will have to be changed. Sometimes the strainer ahead of the capillary tube is restricted, not the tube itself. Normally the outlet of the filter should be warm because the refrigerant has not yet begun to flash. A restricted filter will be cool at its outlet. In this case, changing the strainer or filter should fix the problem.

Water in low-temperature systems can freeze up at the capillary tube, creating a restriction. The difference is that the water will thaw and the restriction will clear if the unit is allowed to thaw. This does not fix the problem; it only identifies it. A system with moisture will operate correctly until the moisture hits the metering device and freezes. Then the suction pressure will drop, the superheat will rise, and the unit will lose its cooling ability. The solution is to recover the refrigerant, replace the filter, pull a good vacuum on the system, and charge the system with clean refrigerant.

17.9 FIXED ORIFICES

The fixed orifice is a newer type of fixed metering device (Figure 17-19). *Orifice* is just a three-syllable word for "hole." Although many names have been used for the small brass piece that has the hole, the most common name is piston. Its operating principle is similar to the capillary tube: a pressurized fluid passes through a small hole, and the resistance to flow through the hole causes a drop in pressure. Since the entire pressure drop occurs at one opening, the size of that opening is all the more critical. Since the pressure drop occurs to some extent throughout the entire length of a capillary tube, its sizing is much less critical than that of an orifice.

The orifice is like the capillary tube in a number of ways:

- It must be carefully selected to match the load.
- The system must be critically charged.

- It permits refrigerant migration into the evaporator during the off cycle and requires all of the same protective accessories as the capillary tube.

Many orifices come in some form of mechanical fitting. On these systems, the orifice is contained in the male fitting on the unit where the liquid line connects (Figure 17-20). The orifice looks like a small, solid brass piston with a small hole. The two chief advantages of these metering devices are economy and flexibility. Since these devices are installed like flare couplings, they can be added after the coil-manufacturing process instead of during manufacture. They can also easily be changed to match specific system requirements. Split-system evaporators that use orifices typically come with an installed orifice that matches the normal condenser match for the evaporator. However, there are usually several correct matches for any condenser. Many split-system manufacturers ship a selection of orifices with the outdoor unit and a sizing chart to help the installing technician select the proper orifice for the application. The sizing charts give the flow-check device size for just about any combination of condensing unit and evaporator coil imaginable. Matching a 3-ton evaporator with a 2-ton condensing unit is possible by simply changing the flow-check piston. This flexibility helps manufacturers and distributors reduce inventory and still cover most applications.

17.10 ORIFICE METERING DEVICES AND HEAT PUMPS

The orifice has the advantage for heat pump applications of operating as both a metering device and a check valve. It meters refrigerant in one direction and allows unrestricted flow in the other direction. When refrigerant is flowing into the coil, toward the piston, the piston will seat and refrigerant will be forced to go through the orifice in the piston (Figure 17-21). When refrigerant is leaving the coil, the piston will unseat, allowing unrestricted flow around the piston (Figure 17-22). Prior to the development of the piston-type metering devices, air-conditioning and heat pump indoor coils were different. Heat pump coils contained a check valve that allowed refrigerant to bypass the metering device in heating. Today most manufacturers use the same indoor coils for both air-conditioning and heat pump applications.

Figure 17-20 The metering device for this evaporator coil is an orifice located inside the liquid line connection.

Figure 17-21 In the forward direction, the piston seats and acts like a metering device.

Figure 17-22 In the reverse direction, refrigeration can flow around the piston for unrestricted flow.

17.11 TROUBLESHOOTING FIXED ORIFICES

Like capillary tubes, fixed orifices can become clogged. Since all the flow restriction is occurring at one point, a very small amount of debris buildup will cause a problem. Like capillary tubes, a clogged orifice will operate with a

low suction pressure, a high superheat, and a high subcooling. Unlike capillary tubes, clogged orifices are fairly easy to change. Debris can also cause orifices to seat improperly and allow too much refrigerant to pass. In this case, the low-side pressure will be high and the superheat and subcooling will both be low.

SERVICE TIP

Many assemblies that hold the orifice and distributor have a screen inside the copper tube leading to the orifice and distributor tubes. This screen is not generally visible without removing the whole assembly. Brazing oxides and contamination from compressor burnouts can clog this screen, making it difficult to locate refrigerant restriction.

Orifices are more likely to be sized incorrectly than capillary tubes because they are more likely to have been installed in the field. An oversized orifice will overfeed, producing high suction pressure, low superheat, and low subcooling. An undersized orifice will cause low suction pressure, high superheat, and high subcooling.

Any orifice problem can usually be solved by recovering the refrigerant; installing a new filter drier; replacing the orifice with a new, correctly sized orifice; evacuating the system; and charging the system with clean refrigerant.

SERVICE TIP

Do not try to clean or resize a metering-device orifice by drilling it out. The orifice in a fixed-restriction metering device should never be drilled out. The orifices are actually conical-shaped holes that you do not have the capability to drill in the field. Drilling an orifice is much more likely to create even worse system problems than existed before the operation. A drilled orifice can easily overfeed, leading to flooding and dead compressors. Simply changing the piston takes less time and is much safer for the system.

17.12 MODULATING METERING DEVICES

A modulating metering device can adjust to changing operating conditions. Modulating metering devices are preferred for systems that have significant load variation. The ability to adjust to changing operating conditions makes these metering devices more efficient than fixed metering devices. Types of modulating metering devices include the following:

- Low-side float (LSF)
- High-side float (HSF)
- Automatic expansion valve (AEV)
- Thermostatic expansion valve (TEV)
- Electronic expansion valve (EEV)

Figure 17-23 (Left inset): Float opens when the level of refrigerant lowers; (right inset): the outlet has a small opening that lets some refrigerant and oil flow back to the compressor to ensure proper oil return to the compressor during operation.

17.13 LOW SIDE FLOAT

In the low-side-float (LSF) metering device, the evaporator is flooded with refrigerant liquid and the level in the evaporator is maintained by a float (Figure 17-23). Their operation is similar to the floats used in toilets. If the load is increased, more refrigerant boils away. This causes the liquid level to drop, and the float lowers and the valve opens wider, allowing more refrigerant into the coil. If the load is reduced, less refrigerant boils away. The liquid level rises as refrigerant continues to enter until the float rises enough to close the valve. The low-side float can be installed in the evaporator or in a separate float chamber.

One advantage of this arrangement is that the heat-transfer rate from a flooded coil is higher than with a mixture of liquid and vapor. One disadvantage is the possibility of oil collecting in the evaporator under light loads and not returning to the compressor.

The low-side float has been rather commonly used on ammonia systems that use flooded evaporators. However, low-side floats are not used on typical air-conditioning or commercial refrigeration applications.

17.14 HIGH-SIDE FLOAT

The high-side float (HSF) modulates refrigerant flow to the evaporator based on liquid level. Unlike the low-side float, this float assembly is located on the high-pressure side of the metering device's orifice. As the load increases, more refrigerant is condensed in the condenser and flows into the high-side float assembly. The valve opens when the liquid level rises in the chamber, permitting greater flow into the evaporator. The pressure-reducing valve, or weight valve, is used in a long liquid line to prevent evaporation before the liquid reaches the evaporator. If the load is decreased, the float is lowered, reducing the flow of refrigerant. The most common application of the high-side float is in the flooded cooler of a centrifugal chiller. Figure 17-24 shows a high-side float controlling refrigerant flow to a flooded chiller evaporator.

Figure 17-24 Diagram of a high-side float refrigerant control. (WITT cold Maschinenfabrik GmbH)

17.15 AUTOMATIC EXPANSION VALVE

Automatic expansion valves (AEVs) are basically refrigeration pressure regulators. They open and close to keep a constant pressure at the valve outlet. This type of valve consists of a diaphragm, a control spring, the valve needle (or ball), and seat (Figure 17-25). The evaporator pressure exerts a force against the bottom of the diaphragm. An adjustable spring exerts a pressure on the top of the diaphragm. When the spring pressure is higher than the evaporator pressure, the diaphragm flexes down, moving the valve pin off the seat. As the evaporator pressure increases, it overcomes the spring pressure and moves the diaphragm up, thus closing the valve.

The valve has an adjustment at the top for setting the evaporator pressure to produce a desired evaporating

Figure 17-25 Automatic expansion valve.

temperature. Turning the adjustment clockwise increases the evaporator pressure; turning the adjustment counterclockwise decreases the evaporator pressure (Figure 17-26).

AEVs do not allow system pressures to equalize on the off cycle. When the compressor shuts off, the evaporator pressure builds up and overcomes the spring pressure, closing the valve. The low-side pressure quickly reduces when the compressor starts operating. The valve does not open until the evaporator pressure is lower than the spring pressure.

AEVs are good for maintaining a specific temperature because they keep the saturation pressure in the evaporator steady. One of the most common uses for AEVs today

Figure 17-26 Turning the adjustment clockwise increases the evaporator pressure; turning the adjustment counterclockwise decreases the evaporator pressure.

Figure 17-27 Automatic expansion valves are often used on refrigerated air driers.

is with refrigerated air driers (Figure 17-27). A refrigerated air drier condenses water out of compressed air. These systems run continuously, even when no air is traveling through them. AEVs allow the evaporator to be as cold as possible without freezing, even when there is no air flowing over the evaporator.

17.16 AUTOMATIC EXPANSION VALVE RESPONSE TO LOAD CHANGES

AEVs respond to changes in the evaporator load, but not in a way that is normally useful. If the load is light, less liquid will boil in the evaporator, causing the evaporator pressure to fall. The valve will open to try and keep the pressure up. This excess refrigerant floods the evaporator, creating a potential hazard for the compressor. Then as the load increases, more liquid refrigerant will boil, raising the evaporator pressure. The valve will close in response to this increased pressure, reducing the flow of refrigerant just when the evaporator could use more refrigerant. This causes the refrigerant vapor going into the compressor to have an increased amount of superheat. The increased suction superheat can cause the compressor to overheat, resulting in high discharge temperature and pressure, oil breakdown, carbonizing of the valves, and poor efficiency.

17.17 THERMOSTATIC EXPANSION VALVE

The thermostatic expansion valve (TEV) is widely used for nearly all types of air-conditioning and refrigeration systems, except for small appliances. The TEV is shown in Figure 17-28. The advantage of the TEV is its ability to automatically adjust to match the load, as it is designed to sense changes in the refrigeration load and respond to them. The TEV is not designed to maintain a constant temperature or pressure. Instead, it is designed to maintain a constant superheat. Imagine a system with an AEV that was monitored by a system operator. The operator could tell how much heat load was currently on the evaporator by monitoring the suction line pressure and temperature leaving the evaporator and calculating the superheat. If the superheat increased, the operator would

Figure 17-28 Construction of a TEV.

increase the spring pressure on the AEV to increase the flow of refrigerant to the evaporator. If the load and superheat decreased, the operator would decrease the spring pressure on the AEV to decrease the flow of refrigerant to the evaporator. The system would be operating at higher pressures and temperatures during periods of high load and lower pressures and temperatures during periods of low loads, but the superheat would remain fairly stable. This is essentially how a TEV works, except the valve, instead of a human operator, monitors the superheat.

Like the AEV, the TEV uses a diaphragm to control the flow of refrigerant. However, the TEV uses a remote bulb instead of spring pressure for the opening force on top of the diaphragm. The position of the valve pin is controlled by three pressures:

1. The evaporator pressure acting on the bottom of the diaphragm to close the valve
2. The spring pressure acting on the bottom of the diaphragm to close the valve
3. The bulb pressure opposing these two pressures and acting on the top of the diaphragm to open the valve (Figure 17-29 shows the relationship among these three pressures.)

The remote bulb is mounted on the suction line, sensing the suction line temperature. The bulb is filled with a volatile fluid whose pressure increases when the bulb temperature increases. On traditional expansion valves, the fluid in the bulb has the same type of refrigerant as that in the system. The bulb pressure is transmitted to the top of the diaphragm via a capillary tube (Figure 17-30). When the suction line temperature increases, the bulb pressure increases the opening force on the valve. When the suction line temperature decreases, the bulb pressure decreases the opening force on the valve. The evaporator pressure is

**Figure 17-29** Basic TEV operation can be expressed as bulb pressure = evaporator pressure + spring pressure.**Figure 17-30** The power head of a TEV, including diaphragm, bulb, and connecting capillary tube.

VALVE WITH EXTERNAL EQUALIZER

Figure 17-31 Evaporator pressure must reach the underside of the diaphragm for the TEV to operate.

supplied to the underside of the diaphragm on the TEV by either an internal passageway or an external line (Figure 17-31). An increase in evaporator pressure increases the pressure on the underside of the diaphragm, increasing the closing force on the valve. A decrease in evaporator pressure decreases the pressure on the underside of the diaphragm, decreasing the closing force on the valve. The addition of a spring on the underside of the diaphragm adds additional closing pressure, producing superheat.

The system is in equilibrium when its operating superheat equals the valve setting and the flow of refrigerant through the valve matches the load. At this condition, the pressure on the bottom of the diaphragm exactly balances the bulb pressure on the top of the diaphragm. For example, an R-410a system, with a suction pressure of 118 psig, a bulb temperature of 50°F, and a superheat setting of 10°F, would be in equilibrium. To calculate the superheat, look up the saturation temperature for 118 psig R-410a: it should be 40°F. Subtract the 40°F saturation temperature from the 50°F actual suction line temperature for the superheat: 50°F – 40°F = 10°F.

Figure 17-32 Evaporator pressure passes through the holes around the triangular push rods on this internally equalized TEV.

17.18 INTERNALLY EQUALIZED VALVES

Thermostatic expansion valves (TEVs) must be able to sense the evaporator pressure to operate correctly. The port or line that transmits the evaporator pressure to the underside of the diaphragm is called an equalizer line. On internally equalized valves, this is done with a passageway through the valve from the valve outlet to the underside of the diaphragm. Often the passageway is nothing more than a clearance around the push rods (Figure 17-32). This type of valve is called an internally equalized valve because the equalizer port is inside the valve. Internally equalized valves are easier to install than externally equalized valves because they do not require any connection to the suction line. However, since internally equalized valves measure the evaporator pressure at the beginning of the evaporator, they will not work well with evaporators that have a large pressure drop. The pressure drop causes the saturation temperature to drop also. The actual saturation temperature at the end of the evaporator will be considerably lower than the saturation temperature the valve sees at the beginning of the coil. This is why internally equalized valves are nor-

mally limited to single-circuit evaporators with a maximum pressure drop that is equivalent to a 2°F saturated temperature drop. Figure 17-33 lists the maximum recommended pressure drop for several refrigerants and evaporator temperatures. Notice that less pressure drop can be tolerated at lower evaporator temperatures than at higher evaporator temperatures.

17.19 EXTERNALLY EQUALIZED VALVES

It is necessary to use an externally equalized thermal expansion valve to obtain an accurate superheat setting when the pressure drop in the evaporator (including the distributor) is

Figure 17-34 Effect of an external equalized TEV on the operation of the system.

sizable (Figure 17-34). Externally equalized valves measure the evaporator pressure through a separate line connected to the suction line. The underside of the diaphragm is isolated from the outlet of the valve so that the only pressure influencing the operation of the valve is the suction pressure coming in at the external equalizer line. To ensure that the valve outlet is isolated from the evaporator side of the diaphragm, the push rods are tightly fitted (Figure 17-35). Externally equalized valves are named for the line external to the valve that provides the evaporator pressure that balances the bulb pressure. Thus, the difference between an internally equalized valve and an externally equalized valve is where the evaporator pressure is sensed. If the evaporator pressure reaches the underside of the diaphragm via a passageway inside the valve, it is an internally equalized valve. If the evaporator pressure reaches the underside of the diaphragm through a separate line external to the valve, it is externally equalized (see Figure 17-31).

External equalizers must also be used when a distributor is used. Distributors are devices that divide the refrigerant evenly between several different refrigerant circuits in a multiple-circuit evaporator. A pressure drop is created across the distributor. This prevents the use of an internally equalized valve because the pressure at the valve outlet will not be the same as the pressure at the evaporator inlet.

Figure 17-35 The push rods on this externally equalized expansion valve fit tightly in the guide holes; evaporator pressure is provided by a separate, external tube and passes through the hole shown in the picture.

17.20 BULB CHARGES

The conventional thermostatic expansion valve (TEV) uses a remote sensing bulb with a mixture of liquid and vapor refrigerant in it. They typically use the same refrigerant that the system uses. However, bulb charges are frequently designed to produce specific operating characteristics that cannot be obtained with a traditional charge. The bulb charge is what primarily determines how a TEV will respond to system changes. The perfect charge for one type of system might be a disaster in another system. TEVs are not plug-and-play devices; they must be carefully selected for their particular application. The types of bulb charges available include the following:

- Liquid charge
- Liquid cross-charge
- Gas charge
- Gas cross-charge
- Adsorption charge

Liquid Charge

Liquid-charged bulbs are the standard. They are charged with the same type of refrigerant as is in the system. Enough charge is put in the bulb so that there is always liquid in the bulb. A liquid-charged bulb will exert an opening force equal to the saturation pressure for bulb temperature. An advantage to this type of charge is that the sensing bulb will never lose control over the valve as can happen with some other types of charge. A disadvantage of this type of charge is that it will cause high suction pressures on system startup and will also cause slow pull-down times.

Liquid Cross-Charge

A cross-charge contains a liquid that is different from the system refrigerant, usually a mixture of refrigerants. The components in the bulb charge are selected to produce a pressure response that is different from the saturation curve of the refrigerant in the system. If the bulb response and the refrigerant saturation pressure were graphed, they would cross each other at some point; thus the name *cross-charge*.

A valve with a traditional liquid charge requires more superheat to open at low pressures than at higher pressures. Liquid cross-charges help address this by flattening out the valve response. Valves with liquid cross-charges require about the same amount of superheat to open at low temperatures as at higher temperatures. Liquid cross-charges are often used on commercial refrigeration systems.

Gas Charge

A standard gas charge uses the same refrigerant as is in the system but does not have enough liquid refrigerant in the bulb to ensure liquid at all temperatures. At normal operating temperatures, the gas-charged bulb will respond more quickly than a liquid-charged bulb because of the limited charge in the bulb. The liquid will all be vaporized at or above the maximum operating pressure of the valve. Additional temperature rise will produce very little pressure rise because there is no more liquid in the bulb to vaporize. This is used to produce a valve with a maximum operating pressure.

A potential problem with this charge is that the liquid refrigerant can migrate from the bulb to the diaphragm if the valve body becomes colder than the sensing bulb. Once the liquid has migrated to the diaphragm, the sensing bulb no longer controls the valve operation.

Gas Cross-Charge

A gas cross-charge uses a refrigerant or mixture of refrigerants that are different from the system refrigerant. There is limited charge in the bulb, giving this type of charge a maximum-operating-pressure feature. The pressure response of a gas cross-charge is different from a traditional gas charge because the fluid in the bulb is different. One application of a gas cross-charge is to produce a flat response at normal operating pressures and temperatures and still have a maximum operating pressure.

Gas cross-charges are subject to charge migration just like traditional gas charges. It is important that the bulb remain cooler than the valve body.

Adsorption Charge

The adsorption charge uses an adsorbent material in the bulb and a noncondensable gas charge. The amount of gas the adsorbent material will adsorb depends upon its temperature. It tends to adsorb more gas at lower temperatures and release gas at higher temperatures. The variation in the amount of gas adsorbed changes the gas pressure in the power element. One advantage of this type of charge is that it will not lose control due to charge migration because there is no adsorbent in the diaphragm. However, the adsorption charge will not provide a maximum operating pressure.

17.21 MAXIMUM OPERATING PRESSURE (MOP) VALVES

The conventional sensing bulb can cause operating problems during the off cycle as well as on startup. This type of charge can cause excess pressure buildup in the evaporator during the off cycle, causing compressor overloading on startup. When the system starts, the valve opens wide because the suction line is warm, creating high suction pressures that can overload the compressor. This can be prevented by using a maximum operating pressure (MOP) valve. As the name implies, the valve has a maximum pressure that it will let through, regardless of the superheat. MOP valves have a gas-charged sensing bulb. The charge in the bulb is a mixture of liquid and gas at normal operating conditions but turns to all gas at the maximum operating pressure point (Figure 17-36). An increase in temperature of a vapor past the normal operating temperature range produces only a slight increase in pressure. Nearly all air-conditioning systems using TEVs limit the amount of pressure that can develop in the evaporator.

17.22 VALVE SUPERHEAT SETTING

All systems do not operate at the same superheat setting. The "correct" superheat for any system can only be determined by consulting the equipment manufacturer.

Figure 17-36 There is a small amount of liquid at normal operating temperatures in a gas-charged valve with MOP. When the temperature reaches the MOP point, all the liquid has vaporized, so the pressure levels off.

However, there are standards that are widely used throughout the industry. First, a lower superheat setting delivers a higher capacity by using more of the evaporator coil to boil refrigerant. All systems should operate at the lowest possible superheat that will ensure dry vapor returning to the compressor. Next, the desired operating superheat decreases as the temperature difference between the evaporator and the load decreases. The evaporators in low-temperature refrigeration systems operate as little as 5°F lower than the freezer they are cooling, while the evaporators in air-conditioning systems can be 40°F cooler than the air they are cooling. Low-temperature freezers often operate with superheat as low as 4°F, while air-conditioning systems typically have superheat settings as high as 15°F. In general, the lower the operating temperature, the lower the normal operating superheat. As always, the manufacturer's recommendations should be the deciding factor in what a superheat setting should be. One manufacturer recommends 3–5°F superheat for low-temperature systems, 5–9°F superheat for medium-temperature systems, and 10–15°F superheat for high-temperature systems. An all-purpose superheat for generic refrigeration systems would be somewhere around 10°F.

Many manufacturers put nonadjustable TEVs on their systems (Figure 17-37). These valves have no provision for adjusting the superheat because the manufacturer has them made for one particular application. Most over-the-counter valves are adjustable. They typically have an adjustment stem, as in Figure 17-38, or an adjustment screw, as in Figure 17-39. They usually come from the factory set between 8°F and 12°F. These valves may need setting when they are installed because they are not manufactured for any particular system.

Figure 17-37 Some TEVs are not field adjustable.

Figure 17-38 Most adjustable TEVs have square adjustment stems that must be turned with a refrigeration wrench.

17.23 MEASURING SUPERHEAT

Operate the system long enough for the system pressures to stabilize before trying to read the superheat. This can take 15–30 min. To adjust a TEV accurately, it is first necessary to measure its operating superheat. The basic formula for determining superheat is

$$\text{superheat} = (\text{suction line temperature}) - (\text{evaporator saturation temperature}).$$

This is illustrated in Figure 17-40.

Suction line temperature can usually be obtained quite easily by measuring the temperature of the suction line at or near the expansion valve bulb. The temperature should be measured at the bulb since that is the point at which the valve is measuring the suction line temperature. An accurate electronic thermometer is recommended (Figure 17-41). Infrared thermometers are usually not accurate for suction line temperature measurements. The line is usually

Figure 17-39 Some adjustable TEVs have adjustments that are turned with a screwdriver.

smaller than the smallest point they can focus on, and the surface emissivity of the copper tubing is not close to the 0.95 that most infrared thermometers expect.

Evaporator saturation temperature is not as easily measured. To begin with, just getting to a spot where the

4. SUPERHEAT = TEMP. LEAVING — SATURATION TEMP.

Figure 17-40 Superheat is measured by subtracting the evaporator saturation temperature from suction line temperature.

Figure 17-41 Clamp-on thermocouple temperature probes can be used to get an accurate suction line temperature measurement.

evaporator saturation temperature can be measured is usually not practical. Therefore, the saturation temperature must be approximated since it cannot be directly measured. Second, the saturation temperature does not remain constant throughout the evaporator because the pressure does not remain the same. The most accurate way to determine the saturation temperature of the evaporator is to measure the suction pressure as close to the outlet of the evaporator as possible. If appreciable pressure drop exists between the evaporator outlet and where you actually measure the suction line pressure, this pressure drop must be added to the actual pressure reading to obtain an accurate evaporator saturation pressure reading.

Next, refer to a pressure/temperature chart to determine the evaporator saturation temperature (Figure 17-42). Finally, subtract the evaporator saturation temperature from the suction line temperature: the difference between the two is the operating superheat of the valve.

The obvious limitation is knowing the pressure drop between the outlet of the evaporator and the nearest suction line port. On split systems, this is usually outside at the condensing unit. Standard line sizing practice is to design for a 2°F saturated temperature drop in the suction line. The amount of pressure would vary depending upon the evaporator temperature and type of refrigerant. The pressures in Figure 17-33 will apply here as well. Some manufacturers do provide a pressure tap at the indoor coil, making the process much easier (Figure 17-43).

17.24 ADJUSTING VALVE SUPERHEAT

Before attempting to adjust the superheat on an expansion valve, make sure that some other system problem is not causing the incorrect superheat. Adjusting a valve that does not need adjusting will just create another problem to solve once you have solved the original problem. For example, a high superheat can be caused by a system undercharge or a liquid line restriction. The valve cannot feed more refrigerant if it is not available. On the other hand, a system with a very low load may have a low superheat.

The superheat is adjusted by turning the valve stem in small increments to change spring tension. Increasing the spring tension increases the superheat setting; decreasing the spring tension decreases the superheat setting. The adjustment on most valves is clockwise (cw) to increase superheat and counterclockwise (ccw) to decrease superheat (Figure 17-44). Small adjustments can make big changes, especially if the operating superheat is within a few degrees of the desired superheat. Usually a quarter turn at a time is sufficient. A half turn might be warranted if the setting is off

Figure 17-43 The coil has a Schrader valve connection that can be used to take an accurate evaporator saturation-pressure reading.

by 10°F or more. Time is required after each adjustment for the system pressures and temperatures to stabilize. This is an operation where being patient and taking your time will save time in the long run.

17.25 LIQUID DISTRIBUTORS

The refrigerant leaving the expansion valve must be distributed evenly to each circuit of multiple-circuit coils. This cannot be done using a common header because the refrigerant leaving the metering device is a mixture of liquid and gas. Since the liquid and gas are different densities, they will not flow through the header the same way. The result will be that some circuits are flooded while others

Figure 17-46 The distributor has a conical point that spreads the refrigerant evenly to all its circuits.

are starved. Distributors are used to equally distribute the refrigerant to each circuit on a multiple-circuit coil. They are placed between the expansion valve and the evaporator, as shown in Figure 17-45. Distributors are usually supplied by the coil manufacturer and are used where one metering device serves from two to forty evaporator circuits, using connecting tubes ranging from $\frac{5}{32}$ in OD to $\frac{3}{8}$ in OD. The distributor consists of a nozzle, a conical divider, and multiple holes evenly spaced around the divider cone (Figure 17-46). The liquid and gas are evenly mixed when they pass through the nozzle. This homogenous mixture is then split evenly by the divider cone, which sends equal amounts to each of the holes around it.

There is a pressure drop across the distributor. The effect of the distributor pressure drop is to reduce the amount of pressure drop across the expansion valve. Expansion valves with external equalizers must be used when a distributor is used because the pressure leaving the valve is higher than the pressure entering the evaporator coil.

17.26 LOW LOAD LIMITS

Both distributor nozzles and TEVs have low load limitations. A distributor will usually operate properly between 50 and 200 percent of its design capacity. When the flow through

the nozzle drops below 50 percent, the gas and liquid refrigerant are not equally mixed. The superheat in the top circuits of the evaporator can be excessive due to liquid starving. The liquid floods back to the compressor from the lower circuits. This can easily be checked by measuring the temperature difference between the top and the bottom circuits of the coil. This problem can sometimes be solved by replacing the nozzle with the next smaller size.

The minimum load for most traditional TEVs is 35–50 percent of their capacity. When the flow through a TEV drops below 30 percent, the valve will not hold constant settings. The valve will alternately overfeed the coil and then underfeed the coil. This condition is called hunting. Under these conditions, superheat values fluctuate. Using a smaller expansion valve can sometimes correct this condition.

Systems that must operate over a wide capacity range can solve the problem of underloading the expansion valve and distributor by using two expansion valves and distributors. Each valve would be sized for approximately 50 percent of the coil capacity. The control system can operate a solenoid to cut off one section of the evaporator when the load drops below 50 percent capacity.

17.27 BALANCED-PORT EXPANSION VALVES

The primary reason for the operating limits of traditional TEVs is the design of the port and pin in the valve. Typically, the valve pin seats in a hole to oppose flow through the seat. The pressure on one side of the seat is much higher than on the other. This pressure difference acts as another opening force, lifting the pin off the seat. The problem is that this extra opening force changes as the system pressure drop changes. When the head pressure decreases, the pressure drop across the port decreases, and the lifting force decreases. The result is less refrigerant flow and a starved evaporator. When the evaporator pressure decreases, the pressure drop increases, increasing this lifting force. The result is a flooded evaporator.

A solution to these problems is to design the port in the expansion valve to minimize the effect of pressure drop across the valve. These valves are called “balanced port” or “double ported” valves. Although there are several designs of balanced-port valves from different manufacturers, the operating concept remains the same: refrigerant inlet pressure is applied at more than one point on the modulating assembly so that it counterbalances itself. Balanced-port valves can operate within a much wider range of operating conditions, including both low-ambient and low-load operation. Balanced-port valves can typically operate properly on air-cooled condensers down to 35°F without the need for condenser-head pressure control. They can modulate correctly down to 15 percent of full evaporator load.

17.28 BI-FLOW EXPANSION VALVES

For years, expansion valves have been one-way devices: they were made to only operate in one direction. Most still are designed this way. However, TEVs are now available that are specifically designed to allow refrigerant flow in both directions. Some of these valves meter the refrigerant

Figure 17-47 Bi-flow expansion valves are used in water-source heat pumps because they meter refrigerant in both directions.

in both directions, while others have built-in check valves that allow unrestricted flow in the “reverse” direction.

Valves that meter in both directions are used in close-coupled systems, like water-source heat pumps (Figure 17-47). This way the system can be manufactured with a single metering device. Since these valves meter in both directions, they are not directional. These valves must be externally equalized, and the equalizer line must run to a common suction that is suction in both heating and cooling. Likewise, the sensing bulb must be attached to a suction location that is always on the low side, regardless of the operating cycle.

The valves with built-in check valves are typically used with split-system heat pumps (Figure 17-48). This eliminates an external check valve that would normally be used to bypass flow around the expansion valve in the reverse direction. Even though these are also called bi-flow valves, they are directional because they meter refrigerant in one direction and let it flow unrestricted in the other direction.

17.29 THERMOSTATIC EXPANSION VALVE SIZING

Although most TEVs are labeled with a nominal capacity, the operating conditions used to produce this rating may not match the actual operating conditions for the system the valve will be installed in. Extended capacity charts give the valve ratings after considering all the factors that affect the valve capacity (Figure 17-49). The factors that affect the valve capacity are as follows:

- The type of refrigerant
- The evaporator temperature
- The pressure drop across the valve
- The actual temperature of the liquid entering the valve

Refrigerant Type

Selection charts are typically organized by refrigerant type, with a different selection chart for each refrigerant type.

Figure 17-48 Expansion valves with built-in check relief valves are used on air-source heat pumps at both the indoor coil and outdoor unit.

The heading of the table in Figure 17-49 specifies that this table is for R-410a valves. Sometimes refrigerants with similar operating characteristics are grouped together on the same selection chart.

Evaporator Temperature

A range of possible operating evaporator saturation temperatures is listed under each type of refrigerant. A typical selection chart has columns for temperatures from 50°F to –40°F. Select the column that is closest to the evaporator saturation temperature for the system. In general, the valve capacity will decrease as the evaporator saturation temperature decreases.

Pressure Drop Across the Valve

A range of possible operating pressure drops across the valve is listed under the evaporator temperature column. In Figure 17-49 there are six pressure drops to choose from under each temperature column. The highlighted 160 psi column under the 40°F temperature column is the nominal rating condition for these valves. To determine what the pressure drop at the valve will be, start by determining the condenser and evaporator saturation temperatures for the system. Convert these saturation temperatures to pressures using a saturation pressure/temperature chart. Subtract the evaporator pressure from the condenser pressure. Next, subtract any additional pressure drops that do not occur at the expansion valve, including the following:

- Pressure drop through the refrigerant lines
- Pressure drop across any accessories in the liquid line, such as filter driers
- Pressure drop due to vertical lift in the liquid line
- Pressure drop through the distributor if a distributor is used

Looking Up the Correct Nominal Size

Look under the pressure-drop column that most closely matches the actual pressure drop across the valve. Go down the column until you find an actual capacity that is close to the capacity needed. Frequently the desired capacity falls between two valve ratings. In general, a slightly smaller valve will control better than a slightly larger valve. Look to the left to find the nominal size of the valve that

delivers the correct capacity at the system's specific operating conditions. The extended sizing tables can also be used to determine what the actual capacity of any particular valve is at any given condition.

Actual Liquid Temperature

Most valve extended-capacity charts assume a liquid temperature of 100°F. Correction factors are applied to the capacities listed in the extended-capacity chart for liquid temperatures other than 100°F (Figure 17-50). Take the case of a 3-ton nominal-capacity R-410a valve with an evaporator saturation temperature of 20°, a pressure drop across the valve of 200 psi, and an entering liquid temperature of 80°F. In Figure 17-49, the 3-ton nominal-capacity valve has an actual capacity of 3.3 tons at 20°F with a pressure drop across the valve of 200 psig. The liquid correction factor shown in Figure 17-50 for 80°F R-410a liquid is 1.06. The capacity of the valve would be $3.3 \times 1.06 = 3.5$ tons. On the other hand, if the liquid were 120°F, the correction factor from Figure 17-50 would be 0.93. Then the valve capacity would be $3.3 \times 0.93 = 3$ tons.

17.30 INSTALLING THERMOSTATIC EXPANSION VALVES

A TEV should be mounted as close to the evaporator as is practical. When using a distributor, it should be mounted directly to the expansion valve outlet. The valve body itself can be in any position, but it should be in a position that allows access to the adjusting stem in case the valve needs setting. Be careful when soldering or brazing in an expansion valve. The valve body can be wrapped with wet rags or heat-absorbing paste to keep it cool. In particular, the power head and bulb should not be overheated.

SERVICE TIP

Many air-conditioning manufacturers are now supplying evaporator coils for high-efficiency units with TEVs installed inside the case of the coil. The thermal bulb is already attached to the suction line inside the coil. It is easy to destroy the expansion valve when brazing in the suction line on these coils. The heat conducts through the suction piping to the bulb, which is fastened to the suction line on the other side of the coil casing. The pressure created from the extreme heat destroys the valve. When possible, remove the bulb from the suction line before brazing the suction line, and then reattach it when the line cools.

Figure 17-51 The sensing bulb should be mounted at the four- or eight-o'clock position on lines that are $\frac{7}{8}$ in outside diameter or larger.

Bulb Location

The thermal sensing bulb should ideally be located on a clean, horizontal section of suction line as close to the evaporator as possible. The sensing bulb should never be located on the bottom of the suction line. Liquid and oil can puddle at the bottom of the line and affect the temperature on the bottom of the line. The bulb is normally mounted at the four- or eight-o'clock positions on suction lines that are $\frac{7}{8}$ in OD or larger (Figure 17-51). The bulb may be mounted anywhere except on the bottom on lines that are smaller than $\frac{7}{8}$ in OD.

If a vertical bulb installation cannot be avoided, the bulb may be installed on a descending vertical line with the capillary-tube end at the top (Figure 17-52). The bulb should never be located in a trap or downstream from a trap. Liquid collecting in the trap can throw off the temperature reading at that point.

Good thermal contact is essential for the valve to operate correctly. The bulb should be fastened to the line with copper straps that will not only hold the bulb securely but will also help improve the thermal contact between the line and the bulb. Finally, the bulb should be insulated from the surrounding air so that the temperature the bulb is sensing is the suction line temperature, not the air temperature.

External Equalizer Connection

If a valve has an external equalizer, it must be connected; an externally equalized valve cannot operate without its equalizer line being connected. The equalizer connection

Figure 17-52 The capillary tube should come off the top if the bulb must be mounted on a vertical line.

Figure 17-53 The external equalizer connection should come off the top of the suction line, downstream from the bulb.

normally penetrates the suction line 6 or 8 in downstream from the sensing bulb, unless the manufacturer's instructions advise differently. The equalizer line should come off the top of the suction line, never off the bottom (Figure 17-53). Piping the equalizer off the bottom creates a potential trap that can interfere with the proper operation of the valve.

SERVICE TIP

The external equalizer line should never be upstream of the bulb. Although refrigerant is not supposed to flow through the equalizer line from the expansion valve, small internal leaks in the valve can allow a small flow of liquid through the equalizer line. If the equalizer line enters upstream of the bulb, this small flow of liquid can fool the bulb into thinking there is liquid leaving the evaporator. This will cause the valve to underfeed and starve the evaporator.

17.31 TROUBLESHOOTING THERMOSTATIC EXPANSION VALVES

TEV problems fall into three general categories:

- The valve overfeeds, flooding the evaporator.
- The valve underfeeds, starving the evaporator.
- The valve hunts, alternately overfeeding and underfeeding.

Valve Overfeeding

Valve overfeeding is most often caused by incorrect thermal bulb installation. The valve overfeeds because it cannot accurately sense the suction line temperature. The thermal bulb should be securely fastened to a straight, clean, horizontal section of suction line. The bulb should also be insulated from the surrounding air. The bulb should sense the suction line temperature, not the air temperature. If a bulb is loose or poorly insulated, it will be reading a temperature that is higher than the suction line temperature, and the valve will overfeed. Overfeeding can also be caused by improper valve sizing, incorrect application, or improper adjustment. In the case of valves that are assembled in the field from a kit of components, improper component selection can easily result in overfeeding. However, before investigating any of these possibilities, make sure the sensing bulb is correctly installed and insulated.

Valve Underfeeding

Check the system charge before assuming that the expansion valve is underfeeding. A valve cannot supply refrigerant that is not there. Also check for restrictions in the liquid line such as a plugged filter drier. Typically, a restriction in the liquid line will cause a temperature drop across the restriction. This can be assessed by checking the temperature difference across the suspected restriction.

A common cause of underfeeding on valves in systems with HFC refrigerant and POE lubricant, such as R-410a systems, is clogged screens and valves. Many valves have screens at their inlet to prevent foreign debris from entering the valve. A system with scale inside the lines caused by brazing can become clogged with this scale when the refrigerant and oil scrub it off the inside of the refrigerant lines and deposit it at the expansion valve. If the valve does not have a screen, the debris may become lodged in the valve itself. This usually requires changing the valve. One equipment manufacturer has had so many problems with debris-clogged valves that they now require the liquid line filter to be installed as close to the indoor unit as possible.

A TEV that has lost the charge in its bulb will underfeed severely. Often, systems that have valves with dead power elements will pull a vacuum on the low side. One way to diagnose a dead power element is to remove the bulb from the suction line and hold it in your hand during system operation. The suction pressure should rise. If there is no change, the power element is probably dead. Some valves have replaceable power elements. The parts on the valve shown in Figure 17-54 can be replaced. The entire valve must be replaced on one-piece valves (Figure 17-55).

Figure 17-54 The power head on some expansion valves can be replaced.

Figure 17-55 Some TEVs are constructed with a one-piece body; if the power head dies, the entire valve must be replaced.
(Courtesy Emerson Climate Technologies)

Valve Hunting

A valve that is too large for the load it is trying to control will alternately overfeed and underfeed the evaporator. This happens when the smallest amount that the valve can open lets too much refrigerant through. When the valve opens to minimum position, it floods the evaporator. It will sense this and then shut. This causes the evaporator to starve. It will then sense this and open again. The low-side pressure will actually rise and fall on systems with severe hunting problems. Hunting is usually the result of an oversized valve or a lower than normal evaporator load.

SERVICE TIP

Manufacturers that sell systems with orifice metering devices often offer high-efficiency upgrade kits that can be field applied to their units. These kits are essentially a TEV with all the necessary fittings to connect it to the system. Replacing the orifice with a TEV increases the efficiency of most units by about 1 point on the SEER rating: a 12-SEER unit with a fixed restriction becomes a 13-SEER unit with an expansion valve. Remember that the charging chart on the units are for the orifice, not the TEV that was just installed. The charging charts on an orifice unit will not work with a TEV. Typically orifice charging charts specify the operating superheat at different conditions. Since TEVs try to maintain a stable superheat, these charts will not work with a TEV. Normally there is a statement to this effect in small print somewhere beside the charging chart. A few manufacturers provide a new chart to paste on the panel, but most do not.

17.32 ELECTRONICALLY CONTROLLED EXPANSION VALVES (EEV)

A number of mechanisms have been developed to control refrigerant flow with electric valves. Electronically controlled valves sense the evaporator saturation temperature and the suction line temperature using thermistors (Figure 17-56). A thermistor is a device that changes resistance when its temperature changes. The thermistors are wired to electronic controls that control the operation of the valves. One advantage of using electronic temperature sensing is being able to have the valve and the temperature-sensing device in different locations. These valves are all controlled by electronic signals, but the mechanisms used are quite different from one another. Types of electronically controlled valves that have been successfully applied include the following:

- Pulse-width modulated solenoid valves
- Magnetically controlled analog valves
- Heat motor valves
- Stepper motor valves

Pulse-Width Modulated Solenoid

A pulse-width modulated solenoid valve is shown in Figure 17-57. Unlike the TEV, which can modulate to positions between fully open and fully closed, solenoid valves are either

Figure 17-56 Thermistors are used to sense the line temperature for electronically controlled valves.

Figure 17-57 Pulse-width modulated solenoid valve. (Courtesy of Danfoss, Inc.)

open or closed. Pulse-modulated valves control flow by increasing or decreasing open time during each cycle. When coupled with the proper electronic control system, a solenoid valve can pulse rapidly, opening and closing quickly in response to the cooling load. The illustration on the left in Figure 17-58 shows the valve closed, and the solenoid valve is de-energized; the view on the right shows the energized condition. This valve also serves the function of a liquid line solenoid valve, blocking flow to the evaporator during the off cycle and at other times when refrigerant flow is not required.

Magnetic Analog Valves

The magnetic analog valve is really a specially designed solenoid valve that can modulate. It is controlled by a variable

Figure 17-58 Pulsating solenoid valve, both energized and de-energized.

magnetic field. These valves have been used successfully in transport refrigeration, but they are not common. They are difficult to control, and their repeatability is poor.

Heat Motor Valves

Heat motor valves operate somewhat like traditional TEVs. They are filled with a fluid that expands when it is heated and contracts when it cools. A small heater that is controlled by an electronic circuit is immersed in the fluid. When the heater heats the fluid, it expands and increases the valve's opening force. When less heat is produced and the fluid cools, it contracts, and the opening force is reduced.

Step Motor Valves

The pulse-modulated solenoid valve, the magnetic analog valve, and the heat motor valve all have been successfully applied, but they all share some limitations. Getting consistent control from these is generally difficult. Their repeatability is poor. That is, they do not always behave the same way under the same conditions. All three are essentially fairly old electromechanical technologies being controlled by sophisticated controls.

Step motor valves are truly a more advanced technology. They can deliver more precise control, and their repeatability is excellent. A step motor does not spin like a regular motor but moves in fractions of a revolution, or steps. The motor winding is actually a group of electromagnet pairs. Typically there are anywhere from twenty-four to one hundred electromagnet pairs arranged in a circle around the step motor. The motor moves in steps from one pair of magnets to the next. In the case of a motor with one hundred pairs of magnets, the motor would take one hundred small steps to make one revolution.

An electronically controlled step motor valve is shown in Figure 17-59. The motor shaft rotates in tiny steps to control a set of gears that position a pin in a seat. The operation of step motor valves is governed by the software and electronics used to drive the valve. The step motor gets its signal from an electronic control panel that is attached to an electronic sensor that measures refrigerant superheat. Since the step motor valve is controlled independently of pressure, this valve is able to provide safe startup, shutdown, and operation and high energy efficiency through its full range of operating conditions. One particular step motor valve has 1,596 steps in a 0.125-in stroke and can operate at a rate of 200 steps per second. Not only can this provide very precise control, but the control points are very repeatable. The

Figure 17-59 Step motor expansion valve.

position of the valve pin at five hundred steps will always be the same. As electronic control becomes more popular, more electronically controlled valves will be put into use.

UNIT 17—SUMMARY

The metering device reduces the pressure and temperature of the refrigerant entering the evaporator by restricting how much refrigerant can pass through the metering device. All metering devices have some amount of flash gas. The evaporation of the flash gas helps cool the remaining liquid. The two general types of metering devices are fixed and modulating. Modulating devices can adjust their flow in response to changes in the system; fixed metering devices cannot. The flow through a fixed metering device is not fixed but varies with both the condenser and evaporator temperature. Two types of fixed metering devices are the capillary tube and the orifice. The capillary tube is a small-diameter, seamless copper tube. The orifice is a small, calibrated hole.

Modulating metering devices include the low-side float, the high-side float, the automatic expansion valve, the thermostatic expansion valve (TEV), and the electronically controlled step motor expansion valve. The TEV controls the refrigerant flow to maintain a constant superheat. The three operating pressures affecting TEV flow are bulb pressure, evaporator pressure, and spring pressure. The bulb pressure is balanced by the spring and evaporator pressure. An electronically controlled step motor valve uses a step motor that operates by moving in tiny incremental steps. The step motor operates gears that position the valve pin. Step motor valves are not affected by pressure variables and can provide control with much more precision than traditional TEVs. The electronic controls that operate step motors use thermistors to sense system temperatures.

Service Ticket 1701

Customer Complaint: Poor Cooling

Equipment Type: Recently Installed R-22 Split System with an Orifice Metering Device

A customer has recently installed a new split system. The system does not seem to be cooling well. The technician notices that the high-side pressure is a little low, the low-side pressure is a little high, and both the subcooling and superheat are low. The service technician calls in and asks the installation mechanics if they remember what orifice they used. The installation mechanics reply that they do not know what number the orifice is; they simply left in the orifice that came with the coil. The service mechanic looks up the match between the coil and the condensing unit because the nominal coil rating is 12,000 BTU/hr larger than the nominal rating of the condensing unit. The coil is an AHRI match for the condenser, but the manufacturer specifies a smaller orifice

for the match than is normally shipped with the coil. The technician closes the liquid line valve, pumps the system refrigerant into the condenser, and then closes the suction line valve. The orifice is replaced with the correct size, the coil and line set are evacuated, and the system valves are opened. The unit now operates within manufacturer's specifications.

Customer Complaint: Refrigerator Stops Cooling

Equipment Type: Household Refrigerator with a Recently Replaced Compressor

A customer has just had the compressor replaced in their refrigerator. The refrigerator starts and begins to cool, but it stops cooling a little while after starting. The technician starts the refrigerator and monitors its pressure. The pressures appear normal and the temperature begins to drop. However, after a few minutes the suction pressure pulls into a vacuum and the refrigerator begins to warm up again. The technician notices that although the compressor has been changed, the filter drier appears to be the original. The technician explains that the cause of the problem is most likely moisture freezing at the capillary tube as a result of not getting all the moisture out of the system when the compressor was changed. The refrigerant is recovered, the filter drier replaced, and the system is evacuated and charged with new, clean refrigerant. The refrigerator now stays cold after pulling down.

Service Ticket 1703

Customer Complaint: Air Conditioner Not Cooling

Equipment Type: Newly Installed Split System with a Factory-Installed TEV in the Evaporator Coil

A customer has just had a new high-efficiency air-conditioning system installed. The system uses a thermostatic expansion valve (TEV) that is factory installed inside the evaporator coil. The technician notices that the suction pressure is very low, and both the superheat and subcooling are very high. The system is doing very little cooling. The technician takes the front cover off of the evaporator and removes the TEV bulb from the suction line. The evaporator pressure does not change, even while holding the bulb. The technician notices that the paint on the coil casing is burned around the suction line and that the TEV bulb is installed just on the other side of the coil casing. The technician determines that the TEV power element was destroyed during installation from overheating when the suction line was brazed in. The technician recovers the system refrigerant, replaces the TEV, and evacuates and recharges the system. The suction pressure rises to the factory-specified level, and the system begins cooling.

Service Ticket 1704**Customer Complaint: Poor Cooling and Noisy Compressor****Equipment Type: Walk-in Cooler with a TEV**

A new technician changed the TEV on a walk-in cooler last week. The system owner noticed that the compressor seemed noisier than usual and also noticed that the system was not cooling well. The company's senior technician is sent to see what is going on. There is no superheat, and the evaporator is flooding back to the compressor, causing the noise and poor cooling. The technician decides to check the bulb installation and finds that insulating gum is between the bulb and the suction line, keeping the bulb from sensing the suction line temperature. The senior technician asks the new technician about the gum, and he replies that he was instructed to insulate the bulb well, so he wrapped insulating gum all the way around the bulb. The senior technician explains that the purpose of the insulation is to ensure that the bulb senses the suction line temperature, so insulation between the bulb and suction line is not a good idea. The senior technician corrects the bulb installation, and the system operates with an 8°F superheat and a much quieter compressor.

Evaporators

OBJECTIVES

After completing this unit, you will be able to:

1. identify the four broad categories of evaporator application.
2. discuss the concepts of sensible and latent cooling as they relate to evaporators.
3. explain how bypass air and dehumidification work.
4. list the types of water-cooling evaporators.
5. explain the difference between flooded and direct-expansion evaporators.
6. explain the purpose of the condensate drain trap in air-conditioning evaporators.
7. list the three most common types of defrost in commercial refrigeration systems.
8. discuss the importance of using an evaporator coil that is an AHRI match to the condensing unit with which it is used.

18.1 INTRODUCTION

The evaporator is a device for absorbing heat into the refrigeration system and is named for the refrigerant evaporation taking place inside it. In the evaporator, the refrigerant absorbs heat from its surrounding load as it evaporates from a low-pressure saturated liquid to a low-pressure vapor. The evaporator is a heat exchanger with the refrigerant contained within tubes, passages, or a vessel. The load or product is separated from the refrigerant by the heat exchanger walls or shell. The heat flows into an evaporator because the temperature of the refrigerant is lower than the temperature of the product being cooled. The refrigerant temperature is set by its pressure. The evaporator pressure is maintained by the metering device.

18.2 EVAPORATOR LOADS

In refrigeration, the term *product* refers to anything that is being cooled or frozen, such as food. But it can be used to describe things being manufactured, such as plastics and electronics, health products such as medicines and medical labs, and products that help in manufacturing, such as solvent baths, machining coolants, and hydraulic fluids. It is not normally used to describe air, water, or brine, although they can also be considered products.

The evaporator heat load is the quantity of heat the refrigeration system must remove from the product. The product can be anything that contains a quantity of heat. An evaporator can be used to cool gases, liquids, or solids. Air is the most common gas cooled, water and brine are the most common liquids, and ice or other frozen products are the most common solids.

When evaporator coils are used to cool air, the heat load can be both sensible and latent. The sensible load is the amount of temperature change in the air as it passes through the coil. Sensible heat change results in a temperature change that can be measured by a thermometer.

Most air contains some water vapor. That water vapor will condense to a liquid as it passes over the evaporator if the evaporator temperature is below the dew point. As the water vapor changes from a vapor state to a liquid state, it releases its latent heat to the refrigerant. Latent heat reduces the amount of water vapor in the air. This requires refrigeration capacity, but it does not result in a temperature change in the air. A cooling process that is entirely latent will result in no temperature change in the air. In air conditioning, the load is typically both sensible and latent. Figure 18-1 shows how an increase in latent capacity corresponds to a decrease in sensible capacity.

Dehumidifying the air is the process of removing water vapor from the air. In mechanical refrigeration, water vapor is condensed to form liquid water. Dehumidifying takes a lot

Indoor Wet Bulb Temperature	Total Capacity	Latent Capacity	Sensible Capacity	Temperature Drop
62°F WB	31,000 BTU/hr	0 BTU/hr	31,000 BTU/hr	21°F
67°F WB	34,000 BTU/hr	6,000 BTU/hr	28,000 BTU/hr	19°F
72°F WB	37,000 BTU/hr	16,000 BTU/hr	21,000 BTU/hr	14°F

Figure 18-1 Evaporator sensible and latent capacity vs. entering-air wet bulb.

of energy and can be a major load on a cooling coil. It takes approximately 970 BTU of heat to vaporize 1 lb of water. A pint weighs about 1 lb, so it takes 970 BTU to change it all to vapor. This has the effect of adding 970 BTU of heat to the air. The same quantity of heat, 970 BTU, has to be removed when that water vapor condenses on the evaporator. The cooling capacity that is used to condense water vapor out of the air does not change the air temperature. In humid climates like the southeastern United States, dehumidification is just as important as temperature reduction.

18.3 PRESSURE-ENTHALPY DIAGRAM AND THE EVAPORATOR

A plot of a refrigeration cycle using R410A is shown in Figure 18-2. The line representing the evaporator is shown in green; the lines representing the other three components are shown in gray. Refrigerant enters the evaporator as a saturated mixture at the point indicated by the blue arrow. At this point, the refrigerant is a 30 percent vapor saturated mix with a pressure of 133 psia, a temperature of 40°F, with a heat content of approximately 58 BTU/lb. As the mixture travels through the evaporator, the vapor percentage increases as the liquid percentage decreases. This causes an increase in enthalpy, but the temperature remains 40°F and the pressure remains 133 psia. Eventually, the refrigerant is 100 percent vapor near the end of the evaporator at the point indicated by the purple arrow. At this point the refrigerant is still 133 psia, and 40°F, but its enthalpy has risen to approximately 120 BTU/lb. The last part of the evaporator is used to superheat the refrigerant. By the time the refrigerant leaves the evaporator at the point indicated by the red arrow, the refrigerant has changed to a superheated gas with a pressure of 133 psia, a temperature of 60°F, and a heat content of 135 BTU/lb.

18.4 TYPES OF EVAPORATORS

Evaporators are made for many diverse applications. They can be classified by their application, general operating principle, physical construction, and normal operating temperature

Figure 18-2 Enthalpy change through the evaporator.

range. Evaporators can be grouped by application into four broad categories:

- Domestic refrigeration
- Commercial refrigeration
- Air conditioning
- Chillers

Domestic refrigeration includes household appliances such as refrigerators, freezers, and dehumidifiers. Figure 18-3 shows evaporators for two domestic refrigeration appliances. The top picture is the evaporator for a dehumidifier; the bottom picture is the evaporator for a frost-free refrigerator. Notice that they are both constructed of aluminum.

Commercial refrigeration would be the large refrigerated cases and freezers in grocery stores and restaurants (Figure 18-4). Air-conditioning coils would include residential and light commercial air conditioners and heat pumps. Chillers are systems that cool water or water and antifreeze solutions (Figure 18-5). Each of these groups can be broken down further by such characteristics as physical construction, operating principle, or normal temperature range.

Domestic and commercial refrigeration evaporators can be listed both by their construction and operating

Figure 18-3 Two aluminum domestic refrigeration evaporators.

temperature range. By construction, the types of domestic refrigeration evaporators are as follows:

- Bare pipe (Figure 18-6)
- Plate (Figure 18-7)
- Tube and fin (Figure 18-8)

Listed by their temperature range, they can be classified as the following:

- High temperature, 47°F to 60°F
- Medium temperature, 28°F to 40°F
- Low temperature, -20°F to 32°F

High-temperature applications are generally for storage of such items as flowers, candy, and dry goods. Medium-temperature applications are typically used for perishable fresh foods that must stay above freezing, such as eggs, produce, and fresh meat. Meat cases actually operate below 32°F, but the meat does not begin to freeze until around 28°F. Low-temperature applications are for ice and frozen food. Everything does not freeze at the same temperature. Ice cream needs to be -20°F to be frozen hard, but ice only has to be 32°F.

Air-conditioning evaporator coils are all tube-and-fin coils operating at about the same temperature range. However, there are many variations of shape and thickness

Figure 18-5 Large-tonage chiller.

Figure 18-6 Bare-pipe evaporator coil with gravity air circulation.

in tube-and-fin air-conditioning coils. Figure 18-9 shows the four most common types of air-conditioning coil shapes:

- Slab coils (top left)
- Slant coils (top right)
- "A" coils (bottom right)
- "N" or "M" coils (bottom left)

Air-conditioning coils can also be listed by the direction that air flows through them. Listed by airflow, they can be as follows:

- Upflow: the air blows up through the coil.
- Downflow: the air blows down through the coil.
- Horizontal: the air blows horizontally through the coil.
- Multi-position: this combines one or more of the other positions.

Figure 18-10 shows the airflow direction for each of these types of coils.

Chiller evaporators can be listed both by their general operation and by their construction. By construction they can be as follows:

- Tube in tube (Figure 18-11)
- Shell and coil (Figure 18-12)
- Shell and tube (Figure 18-13)

Figure 18-13 Direct-expansion chiller; refrigerant tubes, water in the shell.

By operating principle, chillers can be either direct expansion or flooded.

Evaporator design is specific to the intended application. An evaporator that performs perfectly in one application might not work at all in a different application.

18.5 FLOODED AND DIRECT-EXPANSION EVAPORATORS

Two general operating principles are used in evaporator design: direct-expansion evaporators and flooded evaporators.

Direct-Expansion Evaporators

Most air-conditioning and refrigeration systems use direct-expansion evaporators, in which the refrigerant travels through tubing. It enters as a saturated mixture and leaves as a superheated vapor. The refrigerant entering a direct-expansion evaporator is a saturated mixture of liquid and vapor. Generally 25–30 percent of the refrigerant entering a direct-expansion evaporator is vapor. This refrigerant flashed to vapor as it was expanding in the metering device. All the refrigerant is a vapor by the time it reaches the end of a direct-expansion evaporator. The very last portion of a direct-expansion evaporator is used for superheating the refrigerant (Figure 18-14).

Flooded Evaporators

The refrigerant enters a flooded evaporator as all saturated liquid, and there is saturated liquid throughout the evaporator. If an evaporator does not have to superheat refrigerant vapor, it can produce more cooling capacity. Flooded evaporators can circulate more pounds of refrigerant (more cooling capacity) per square foot of heat-transfer surface than direct-expansion evaporators because no evaporator surface needs to be used to superheat the suction vapor. On small systems the difference is negligible, but on very large systems, the increase in evaporator performance can be significant.

Large water chillers use flooded evaporators. (A flooded evaporator is shown in the example in Figure 18-43.) The evaporator in a flooded chiller is basically a large tank full of low-pressure, low-temperature liquid refrigerant with water lines submerged underneath the liquid.

Flooded evaporators typically use a float mechanism as their metering device. One of the advantages of a flooded evaporator is its ability to maintain a very accurate temperature across the entire evaporator surface. Some large ice rinks use flooded evaporators so that the rink temperature can be maintained very closely. This is particularly important for Olympic skating competitions. Skaters can tell the

Figure 18-14 Refrigerant enters this direct-expansion evaporator at the bottom as a saturated liquid/vapor mixture and leaves at the top as a superheated vapor.

difference in ice temperature of a few tenths of a degree. Very cold ice sticks to the skate and is more difficult to glide across than slightly warmer ice.

It is very important to ensure that the saturated refrigerant flowing to the compressor does not contain quantities of liquid that could cause mechanical damage. Flooded chiller evaporators have eliminators whose function is to catch droplets of liquid in the returning suction vapor and prevent them from entering the compressor.

18.6 EVAPORATOR CONSTRUCTION

The three most common types of evaporator construction are the following:

- Bare-pipe evaporators
- Plate evaporators
- Tube-and-fin coil evaporators

Bare-Pipe Evaporators

Bare-pipe evaporators are used in domestic upright freezers. The evaporator tubing also serves as the freezer shelves. In commercial refrigeration, bare-pipe evaporators may be used for low-temperature refrigeration, liquid cooling, ice skating rinks, and thermal storage applications. Because air is not blown across low-temperature bare-pipe evaporators, ice buildup on them will not significantly reduce the evaporator's efficiency, unless the ice becomes very thick.

Plate Evaporators

Plates such as those shown in Figure 18-15 are a special form of extended heat-transfer surface used in refrigeration and freezer applications. The plate surfaces may be fabricated in a variety of shapes. The refrigerant passages are formed into the evaporator plates. The most common process for manufacturing plate evaporators is called roll-bond. This type of panel starts as two aluminum sheets. The two sheets are bonded into a single piece by rolling them together. The refrigerant circuit is printed onto the sheets with graphite before the sheets are bonded. After

rolling, the channels are created by pressurizing the panel at between 1,500 and 2,250 psig.

Plate evaporators can also be made by brazing tubing to the plate (Figure 18-16). Either way works well as long as the mechanical contact between the plate and the refrigerant passages is tight. A tight connection is needed for good thermal conductivity of heat from the plate to the refrigerant.

SERVICE TIP

Many plate evaporators are used in small residential refrigerators. Under-the-counter refrigerators do not defrost automatically. When manually defrosting these units, individuals often puncture the evaporator refrigerant passages with a sharp metal object. These punctures can be repaired using a two-part epoxy specifically designed for repairing holes in plate evaporators. Follow the manufacturer's instructions on using the epoxy, and only use those epoxies specifically designed and approved for this application. Some epoxies may have toxic substances that would not be appropriate to have in a domestic refrigerator freezer where food is stored.

Tube-and-Fin Coils

The most common evaporator for cooling air is the tube-and-fin coil. This applies to small refrigerated reach-in and walk-in boxes, as well as to small and large comfort air-conditioning units. The most common tube material is copper.

Fins are added to the copper tubing to increase the surface area. This is done to help accelerate the heat transfer rate into refrigerant evaporator tubes when cooling air. Air is not good as a conductor of heat. By adding tight-fitting aluminum fins to the refrigerant circuit's copper tubes, the air-side surface and corresponding heat transfer can be greatly increased.

18.7 TUBE-AND-FIN COIL CONSTRUCTION

To ensure good heat transfer, the fins must be tightly mechanically bonded to the tubes. The tighter the bond, the better the heat can be conducted from the fins into the refrigerant tubing and refrigerant. The fins are pre-stamped from thin sheets of metal, usually aluminum. They may be left flat or embossed, forming curves or waves in their surfaces. The fin sheets are stacked with even spacing on the copper tubing. The tubes are then mechanically or hydraulically expanded into the tube collar.

The fins are most often formed out of aluminum, but other materials can be used to increase the fins' corrosion resistance. Light protection can be provided with a baked-on powdered coating that is applied to the fin sheets before assembly. The baking process melts the powder, and it flows evenly over the fin surface and bonds much like paint.

It is possible to order coils with special protective coatings for industrial use where ordinary fins may be attacked by corrosion. The heaviest protection is provided when the finished coil is dipped in a thin epoxy. The epoxy cures and covers all of the fins, tubing, and coil headers. These coils provide the longest service in industrial applications where corrosive fumes are present, but they may reduce capacity.

For sprayed-coil dehumidifiers, where water sprays on the coil fins to maintain close temperature and humidity conditions, copper fins would be recommended. Because both the fins and tubing are made from copper, galvanic corrosion is eliminated. This is also important for marine or coastal applications.

Fin Spacing

The distance between fins is called "fin spacing" or "fin pitch" and is expressed as the number of fins per inch. The fin spacing on low-temperature coils can be 1–4 fins per inch to reduce ice bridging. *Ice bridging* is the term for what happens when the ice on one fin joins up with the ice formed on the adjoining fin. As shown in Figure 18-17, it restricts all airflow through the coil.

For air-conditioning applications, fin spacing ranges from 8 to 14 fins per inch. Figure 18-18 compares the fin spacing on a low-temperature refrigeration coil, a medium-temperature refrigeration coil, and an air-conditioning coil. The closer fin spacing produces increased heat transfer per square foot of coil, but the additional fins require more fan energy to move the air through them. This type of tradeoff in design is not unusual.

Tube-and-Fin Coil Tubing

The number of refrigerant tube rows in each refrigerant circuit and their spacing has a great influence on heat transfer in fin coils. The number of refrigerant tubing rows can range from one to ten. Two to four rows are most common for residential and light commercial air conditioning, while commercial air-conditioning coils may have ten or more rows.

Liquid refrigerant absorbs more heat than does refrigerant vapor. There are improvements in the tubing designs to increase the area wetted by liquid, including creating internal tubing grooves. These grooves churn the liquid up

Figure 18-17 Ice bridging between fins on a tube-and-fin coil.

onto the tubing sides as it flows through the evaporator (Figure 18-19). This increases the wetting of the internal tubing walls for better heat transfer. Another improvement has been to make the tubing oval shaped. This, too, increases the area inside the tubing that is exposed to liquid refrigerant.

Tube-and-Fin Coil Thickness

The more rows a coil has, the thicker it is. The thickness of fin coils greatly affects the coil's heat transfer and air resistance. Fin coils range in thickness from 1 in to about 1 ft. Residential and light commercial air-conditioning coils

Figure 18-19 The grooves, or rifling, on the inside of this tubing increase heat transfer by creating turbulent flow.

range from 1 in to 4 in thick. Commercial refrigeration coils may be up to 12 in thick.

Thin coils offer less air resistance and provide mostly sensible cooling. Many high-efficiency air-conditioning coils are built today with only one row of tubing. This provides the maximum possible heat transfer between each tube row and the air. Single-row coils operate at a slightly higher saturation temperature than multi-row coils, so they frequently operate above the dew point. Thin coils offer great economy of operation in arid areas where little or no dehumidification is required.

Thicker multi-row coils are advantageous for nearly all other areas where some degree of dehumidification is required. Multi-row coils use multiple rows of copper tubing held together by aluminum fins (Figure 18-20). The tubing in multi-row coils is staggered so that the front row does not block the airflow to the succeeding rows. Multi-row coils typically operate below the dew point. The air temperature is decreased further because the air that has already been cooled by one tube row is cooled even further by the following tube rows. Multi-row coils offer greater resistance to airflow and require more material to manufacture because their heat-transfer efficiency is less than single-row coils.

Figure 18-18 Comparison of fin spacing on coils for three different applications; the low temperature is on the left, medium temperature is in the middle, and is air conditioning on the right.

Figure 18-20 Multi-row coil used in commercial refrigeration application.

18.8 AIR-CONDITIONING COIL DESIGN

Air-conditioning evaporators use tube-and-fin coils and are manufactured in many shapes, including slab coils, slant coils, "A" coils, and "N" or "M" coils. Slab coils are rectangular in shape and are usually installed vertically or at a slight angle. The airflow through them is horizontal. Slab coils are usually multi-row coils to keep their size down. Slab coils are common in air-conditioning packaged units.

Slant coils are a variation of a slab coil. They are essentially a slab coil installed diagonally (Figure 18-21). Slant coils are usually provided with drain pans that allow both vertical and horizontal installation of the equipment. Slant coils are common in heat pump blower coils.

"A" coils are shaped like the letter A. They look like two slab coils joined at the top (Figure 18-22). "A" coils are popular with split-system air conditioners and heat pumps. Most "A" coils are designed to be installed in the upflow position, with air coming up through the wide opening. Some have been designed for use in counterflow or horizontal positions as well. Most "A" coils are multiple-row coils, but there are many being manufactured today that are single-row coils. These are typically taller because each side must be larger.

Figure 18-21 Slant evaporator used in a heat pump blower coil.

Figure 18-22 Air-conditioning "A" coil.

Figure 18-23 Air-conditioning “M” coil.

Coils shaped like the letter *N* or *M* use many smaller slabs to get more coil surface into a smaller space (Figure 18-23). These coils are typically one- or two-row coils. They are trying to achieve the efficiency improvement of a single-row coil and keep the physical size down.

18.9 TYPICAL AIR-CONDITIONING EVAPORATOR OPERATION

The saturation temperature in an air-conditioning coil is typically 30–40°F below the return air temperature entering the coil. The air temperature drop across the coil is usually between 10°F and 20°F.

For years the standard design evaporator saturation temperature was 40°F at AHRI rating conditions. The standard AHRI rating condition includes 80°F dry bulb and 67°F wet bulb return air. Thus, the evaporators were designed to operate 40°F below the return air temperature at the rating condition. Now many manufacturers are designing the evaporator to operate at 45°F under the same conditions.

The evaporator saturation temperature and the temperature drop across the coil are largely affected by the entering-air wet bulb temperature. A high wet bulb indicates a large amount of water vapor in the air. The condensing of the water vapor on the coil reduces the system’s sensible capacity, so the temperature difference across the coil is decreased.

The evaporator temperature is increased because the air and coil do not get as cold since more of the cooling capacity is going toward condensing water on the coil. Lower entering-air wet bulb temperatures produce the opposite effect. With less latent cooling to do, more of the cooling capacity goes into reducing the air’s temperature. This decreases the coil saturation temperature and increases the temperature differential across the coil.

Standard airflow across an air-conditioning evaporator is 400 CFM (cubic feet per minute) per ton. In general, increasing the airflow across the coil increases the cooling capacity and decreasing the airflow decreases the cooling capacity. However, the airflow can be adjusted to get the correct amount of sensible and latent cooling from the evaporator. Decreasing the airflow increases the percentage of latent cooling capacity and decreases the percentage of sensible cooling capacity. Although both sensible and latent cooling will decrease with decreased airflow, a greater percentage of the cooling will be latent cooling. Increasing the airflow does just the opposite; it increases the percentage of sensible cooling and decreases the percentage of latent cooling. In areas of high humidity, it may be advantageous to sacrifice a small amount of total cooling capacity to increase the percentage of latent cooling capacity in order to control humidity. Equipment manufacturers provide system performance data that show the system’s latent and sensible capacities at different airflow rates (Figure 18-24).

18.10 AIR-CONDITIONING COIL-FACE AREA AND FACE VELOCITY

The face area of a coil limits the face velocity of air that can pass through the coil without causing the water that is condensed on the coil to blow off. *Condensate blowoff* and *moisture carryover* are terms that refer to the small droplets of water that are blown free from the coil and travel a short distance down the duct. Coil manufacturers list the maximum volume in CFM and/or the maximum face velocity in feet per minute (fpm) for each coil they produce. Typically, the air face velocity for coils ranges from 300 fpm to 500 fpm. The face velocity should not exceed 550 fpm. If the condensate blowoff carries past the drain pan, it can leak from the air-handler cabinet and may cause expensive

water damage to the building or its contents. It is important to stay within the manufacturer's published airflow limits to avoid condensate blowoff.

18.11 BYPASS FACTOR

Not all of the air that passes through a coil comes in contact with the coil, even though the fins are very closely spaced. *Bypass factor* is a term used to quantify the air that gets through the coil without touching anything. The bypass factor for a coil is listed as a percentage of the total air volume. Manufacturers often list an evaporator's bypass factor in the performance data (see Figure 18-24).

The bypass factor of a coil affects the coil's ability to cool and dehumidify the air. No moisture is removed from the bypass air that passes through the coil without coming in contact with a cold surface.

There are a number of items that affect a coil's bypass factor, including the following:

- **Fin spacing** The closer the fins are spaced, the lower the bypass factor; the further they are spaced apart, the higher the bypass factor.
- **Fin shape** The greater the fin-embossed curves or waves, the lower the bypass factor; the flatter or straighter, the higher the bypass factor.
- **Coil thickness** The thicker the coil, the lower the bypass factor; the thinner the coil, the higher the bypass factor.
- **Rows of tubing** The number of rows of refrigerant tubing is closely associated with coil thickness. So the more rows, the thicker the coil and the lower the bypass factor; the fewer the rows, the higher the bypass factor.
- **Air velocity** The slower the air speed through the coil, the lower the bypass factor; the faster the air, the higher the bypass factor.

18.12 DEHUMIDIFYING THE AIR

Dehumidifying the air is second to cooling the air as the most important job of tube-and-fin cooling coils. If cooling coils did not remove some of the moisture in the air, our homes and businesses would be cold and damp. It would be like living and working in a cave with mold growing everywhere.

A coil's ability to dehumidify the air is closely associated with a coil's bypass factor. The higher the bypass factor, the lower the dehumidification, and the lower the bypass factor, the greater the dehumidification. The items listed above that affect the bypass factor of a coil, therefore, affect the dehumidification ability of a coil. There are other items beyond those for a coil's bypass factor that affect the coil's dehumidification ability, including the following:

- **Coil temperature** The colder the coil, the more dehumidification; the warmer the coil, the less the dehumidification.
- **Longer run times** The longer the system operates, the greater the dehumidification; the more the system cycles, the less the dehumidification.

- **Parallel air and refrigerant flow** Air and refrigerant can flow through a coil in the same direction—this is called parallel flow. When they flow parallel, the coldest refrigerant is in contact with the warmest air, and the coldest air is in contact with the warmest refrigerant. This results in less dehumidification.
- **Counter air and refrigerant flow** When the air and refrigerant flow in opposite directions through the coil, it is called counterflow. When they flow in opposite directions, the warmest refrigerant is in contact with the warmest air, and the coldest air and refrigerant are in contact. This results in the greatest dehumidification (Figure 18-25).
- **Number of refrigerant circuits** The larger the number of paths refrigerant has through the coil, the higher the dehumidification; the fewer the number of refrigerant paths, the lower the dehumidification.

There are three common ways that manufacturers list a coil's ability to dehumidify the air. One is to list the sensible and latent cooling values for the coil. The second is to list the total cooling capacity and the sensible cooling capacity, with the latent capacity being the difference. The third way is to give the total cooling capacity and give the latent as a percentage of the total. For example, a coil with a nominal rating of 30,000 BTU per hour might have a total capacity of 30,000 BTU, a sensible capacity of 22,000 BTU, and a latent capacity of 8,000 BTU. This would mean that 22,000 BTU are being used to reduce the temperature of the air and 8,000 BTU are being used to condense water on the coil. In this case, the latent capacity is 27 percent, or 0.27 of total capacity.

18.13 PRESSURE DROP ACROSS THE COIL

The term *pressure drop* when applied to a fin coil refers to the difference in static pressure from one side of a coil to the other side. The high side of the incline manometer reads the static pressure of the air entering the coil, while the low side of the manometer reads the static pressure of the air leaving the coil (Figure 18-26). Coil manufacturers publish coil data sheets with this information. The pressure drop across a coil depends on the design of the coil and the amount of air moving over it. All coils produce a higher pressure drop as more air is moved across them. The static pressure drop across an air-conditioning coil is usually the largest single pressure loss in the entire duct system.

The pressure drop, or ΔP (pronounced *delta P*), across the coil is measured in inches of water column. The pressure drop across residential air-conditioning coils is typically less than a half inch of water column. To measure this small amount of a static pressure, you will need an instrument such as an incline manometer or a magnehelic gauge (Figure 18-27). Most manufacturers provide the static pressure for both "wet" and "dry" coil conditions. The term *wet coil* means that the coil is condensing water. The water droplets on the coil fins add to the air resistance and cause a larger static drop across the coil. When taking "wet" coil readings, let the system run for 10–15 min to make sure it

drain by gravity into the drain pan and flow through a condensate drain line to a drain or sink disposal. The drain pans in older coils were often simple rectangular pans under the coil. The drain pans in modern coils are designed to minimize the amount of standing water in the coil by sloping the condensate toward the drain outlet (Figure 18-29). The drain line should be provided with a water seal trap and should never be connected directly to a sanitary drain.

The condensate drain must be trapped to allow the condensate to drain freely. Even when the static pressure in the coil cabinet is positive, the velocity of the air blowing past the drain outlet can create a negative pressure at the drain that tends to hold the water in the drain. This effect is even

Figure 18-29 The sides of this drain pan slant in and toward the drain outlet to reduce the amount of standing water in the drain pan.

more pronounced in draw-through coils where the pressure inside the coil portion of the cabinet is negative to start with.

A condensate drain trap is used to offset the negative pressure at the drain outlet. Standard practice for residential air conditioning includes a 3-in-deep trap. The outlet of the trap should be lower than the outlet of the evaporator drain, and the line leaving the trap should slope toward an open drain or sump. It should not be directly connected to a sewer line. Figure 18-30 illustrates proper condensate drain construction. This design lets the condensate water create a siphon suction pressure equal to the unit's negative static pressure to offset the system's negative pressure so that the condensate water is drawn out of the condensate pan.

SERVICE TIP

Failure to properly design a draw-through condensate trap will allow the negative pressure in the coil drain to stop the condensate from draining. Excessive condensate will then overflow the drain pan, which can cause damage to the structure.

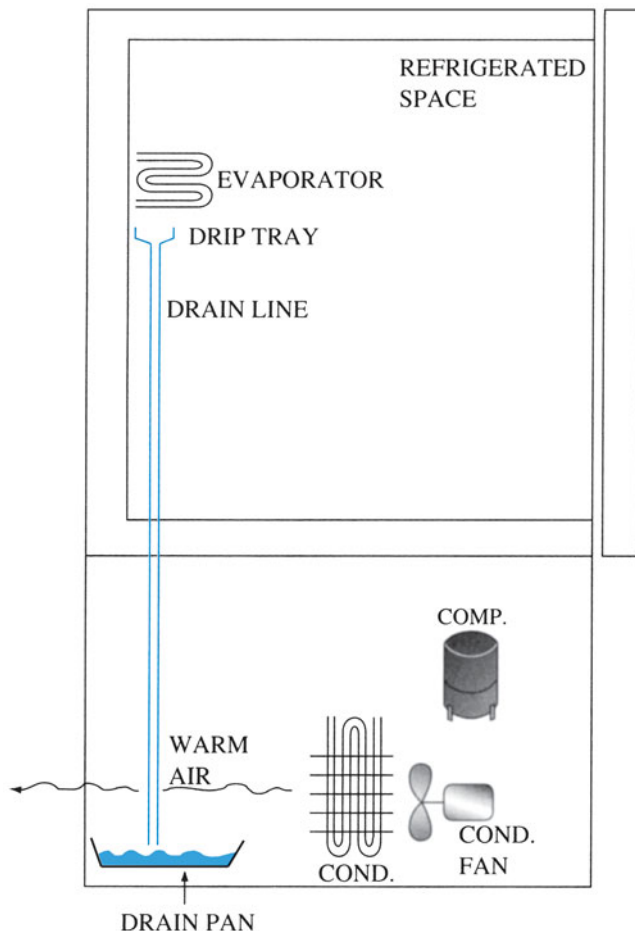

Figure 18-31 Condensate disposal for a refrigerator.

Condensate on refrigerator-freezers can be drained to a tray under the appliance and evaporated by warm air from the air-cooled condenser, as shown in Figure 18-31.

Condensate on package terminal air conditioners (PTAC) and window air conditioners is drained to a sump, picked up by a slinger on the condenser fan, and hurled onto the condenser coil to evaporate (Figure 18-32).

When condensate cannot be drained by gravity, small pumps with a reservoir and float-operated switch can be used to pump the condensate to a nearby drain, as shown in Figure 18-33.

18.15 AIR-CONDITIONING CAPACITY CONTROL

Evaporator coils can be arranged in multiple circuits and the refrigerant flow controlled by solenoid valves in larger systems. Each circuit in a dual-circuited evaporator is fed by a separate expansion valve and distributor. The circuits can be in separate rows, or the coil face can be circuited in two sections. Figure 18-34 illustrates how row and face controls work. Face control is usually preferred for better humidity control (dehumidification). When unloading face control coils, the lower coil section should always be the first on and last off to ensure that condensate will not drain over an inactive section of coil and re-evaporate.

TECH TIP

Capacity control adds efficiency to systems, but the fan speed cannot simply be slowed down as a means of capacity control. This is because as the fan speed slows, less heat is picked up by the evaporator. Therefore the evaporator coil temperature can decrease below the freezing point. Capacity control can be achieved on evaporators by using solenoids to shut down part of the refrigerant circuit within a single evaporator or in an evaporator when there are multiple evaporators in the system.

18.16 COMMERCIAL REFRIGERATION EVAPORATOR OPERATION

Although most commercial refrigeration evaporators are also tube-and-fin coils, their operating characteristics are quite different from air-conditioning coils. The saturation temperature for commercial refrigeration coils is much closer to the temperature of the air they are cooling. Unlike air conditioning, where one of the objects is to reduce the relative humidity of the space, commercial

Figure 18-34 Direct expansion coil, row, and face control.

refrigeration typically tries to maintain a high relative humidity to preserve the food. The evaporator saturation temperature is only 7–22°F colder than the return air entering the evaporator. The higher the desired relative humidity, the lower the temperature difference between

Temperature Differential	Relative Humidity	Product
7–9°F	90%	Vegetables, produce, flowers, ice
10–12°F	80%–85%	Packaged meats, vegetables, fruit
12–16°F	65%–80%	Potatoes, onions, tough-skin fruits

the box and the evaporator saturation temperature. Figure 18-35 shows recommended temperature differentials for typical commercial refrigeration applications.

Frost forms on commercial refrigeration evaporators because they operate below freezing. The fins on a refrigeration coil are spaced much wider apart than on an air-conditioning coil to allow for some frost buildup without too much airflow restriction.

18.17 HOT PULLDOWN

Refrigeration evaporators are sized for the normal operating temperatures of the system. When a freezer or walk-in cooler is first started, the temperature in the box is much higher than the design temperature. This extra heat load causes high operating pressures, high superheat, high compressor amp draw, and overheated compressors. Some equipment manufacturers actually list operating characteristics for a hot pulldown.

Commercial freezers have what amounts to a hot pull-down every time they come out of defrost because the coil is much warmer than normal. Commercial refrigeration systems often protect the compressor from hot pulldown using a crankcase pressure regulator to limit the pressure returning to the compressor.

18.18 TYPES OF DEFROST

Although the wide fin spacing allows air to flow with some frost on the fins, the frost will eventually build up enough to block the airflow. The frost also acts as an insulator and inhibits heat transfer. Commercial refrigeration coils require periodic defrosting to ensure sufficient airflow and cooling.

The amount of frost buildup depends on the condition of the air and evaporator temperature. Open cases build up the most frost because they have a continual supply of warm, moist air. Closed cases that are only opened infrequently build up frost more slowly because new air and moisture only enters the case when the door is opened.

Medium-temperature cases frequently defrost naturally on the off cycle. Their evaporators operate below freezing and build up frost when the compressor is running. However, the box temperature is above freezing, so

the coil defrosts naturally when the compressor shuts off. This works fine unless the operating cycle is extended beyond normal.

Low-temperature cases must have defrost cycles because the frost remains on their evaporators even during the off cycle. The three most common means of defrosting commercial refrigeration evaporators are electric defrost, hot gas defrost, and air defrost. Other less common means of defrost include reverse-cycle defrost and heated water or glycol sprays.

18.19 AIR DEFROST

Coolers that operate at 28–30°F suction temperature will build up frost on the plate fins. They can be defrosted by simply shutting off the refrigeration and letting uncooled air circulate over the coil, as shown in Figure 18-36. Air at 35–39°F will melt the frost. Periodic defrosting can be initiated by a time switch. Air defrosting may go slower than other means, but it uses less energy. Refrigeration units running below 28°F with box temperatures below freezing (32°F) will not air-defrost.

(c)

Figure 18-37 Electric defrost evaporator unit: (a) end cover removed; (b) bottom cover removed; (c) electric resistance pan heater to prevent ice from forming during the defrost cycle.

18.20 ELECTRIC DEFROST

The electric defrost cycle is simple and widely used because of its simplicity and effectiveness. Electric defrost uses electric resistance heaters to melt ice off the coil, the drain pan, and the drain line, as shown in Figure 18-37.

Defrost is usually initiated by a time switch (Figure 18-38), although pressure or temperature sensors have also been used. When defrost is initiated, both the liquid refrigeration solenoid valve and evaporator fan motor are de-energized. The solenoid stops flow through the liquid line and the compressor pumps the system down. The low-pressure switch opens, de-energizing the compressor. At the same time this is happening, the coil heater and drain pan defrost heaters activate. The cycle is usually temperature terminated with a backup-time termination provision to prevent the box from overheating should the temperature control fail for any reason. When the coil reaches the termination temperature, the defrost termination ther-

mostat energizes the termination solenoid in the defrost timer. The evaporator fan is wired through the defrost termination thermostat, which is a single-pole, double-throw switch. The termination thermostat opens the circuit to the evaporator fan when it terminates the defrost cycle. This allows the coil to cool down before the fan comes on. The liquid line solenoid is energized, allowing flow into the evaporator. The pressure increases, closing the low-pressure switch and starting the compressor. Once the coil is cold again, the termination thermostat will close the circuit to the evaporator fan.

18.21 HOT-GAS DEFROST

Using hot gas available from the refrigeration cycle can be an attractive means of defrost. Hot gas is common in large systems with multiple evaporators. A correctly designed hot-gas defrost system is faster than most electric defrost systems. The basic concept of a hot-gas defrost system is

Figure 18-38 Typical commercial refrigeration defrost timer.

that the condenser is bypassed, sending hot gas directly to the evaporator. Returning liquid slugs to the compressor is a potential pitfall with hot-gas defrost because the hot gas can easily condense in the frozen evaporator. This problem is usually addressed in one of two ways:

- The pressure in the evaporator is limited, preventing the gas from condensing.
- The refrigerant is allowed to condense and is then returned to a liquid receiver.

Limited Evaporator Pressure

On single-evaporator systems, hot-gas defrost sets up a short cycle between the compressor and the evaporator. To prevent liquid refrigerant from returning to the compressor, it is necessary to keep the refrigerant from condensing in the evaporator. If the pressure is maintained below the saturation point, the refrigerant will not condense. This type of system feeds hot gas through a side port in the refrigerant distributor, so there is an appreciable pressure drop through the distributor nozzle. This system uses only the sensible heat from the compressor.

Liquid Receiver Return

In a multiple-evaporator system, the evaporator that is defrosting temporarily becomes a condenser. The liquid that condenses in the evaporator is returned to the receiver via the liquid line. This type of system uses an electrically controlled evaporator pressure regulator and a defrost solenoid valve for each coil. When an evaporator coil is being defrosted, the solenoid on the electrically controlled pressure regulator is de-energized, closing the connection to the suction line. The defrost solenoid is energized at the same time, sending hot gas into the evaporator through the suction line. Liquid is condensed in the evaporator and returned through a solenoid to the liquid receiver. A check

valve must be used to allow the liquid to bypass the TEV. Alternately, a TEV with a built-in check valve can be used.

18.22 CONDENSATE DRAINAGE IN COMMERCIAL REFRIGERATION

All defrost systems must have provisions to allow the melted condensate to drain clear of the coil before the system restarts. Otherwise, the condensate can freeze. This can block drain lines and create slabs of ice in the bottom of the evaporator. A time delay between the end of the defrost cycle and the restarting of the compressor and refrigerant cycle helps ensure that all condensate is drained and not refrozen.

Drain lines from condensate drain pans in freezers must be free and clear to handle the drainage during the defrost cycle. The entire drain should be continuously heated by an electric heater cable. They should have a steep pitch (4-in drop per 12-in run) for good drainage and be insulated. Line sizes are typically a minimum of 7/8-in OD tubing, with cleanout tees provided for maintenance.

Heater cable capacity should be sized in accordance with supplier recommendations. A typical capacity is about 6 W per lineal foot. It is also possible to run a hot-gas line strapped to the drain line as a heat source.

SERVICE TIP

Some coils that are used in medium-temperature applications where the space temperature is above 32°F may still form ice because the evaporator temperature is below 32°F. These coils may require some form of defrost either using air or other artificial heating systems, such as electric or hot gas. Coils that ice over without defrost systems may result in a compressor tripping on low pressure. The problem for the technician is when they arrive on the job, the ice has melted and there is no evidence of a problem. For that reason, it may be necessary to temporarily install a temperature recorder on the system to ascertain if the system at times is dropping down below freezing and forming ice. Temperature plotters are available as electronic recorders or paper tape.

18.23 EVAPORATOR EFFICIENCY

The physical construction of the coil affects its efficiency. Decreasing the coil's bypass factor improves the efficiency because more of the air comes into contact with the coil. Decreasing the number of tube rows increases the heat-transfer efficiency of each row because all of the rows are exposed to the warm air.

The closer to the end of the evaporator that the last bit of refrigerant evaporates, the more of the coil is being used to absorb heat. That makes the evaporator perform the most cooling for the highest level of efficiency. However, if there is too little superheat added to the refrigerant, some liquid refrigerant may return to the compressor. *Floodback* is the term used to describe liquid refrigerant flowing back to the compressor. Floodback can cause compressor damage.

Direct-expansion evaporators are commonly fed refrigerant into the lower tubing circuits, and the vapor is drawn out of the top tubing circuits. This reduces the possibility of liquid leaving the evaporator, helping to prevent floodback while still operating at a high level of efficiency.

The overall system efficiency is improved by maintaining as high an evaporator saturation temperature as possible. Higher evaporator temperatures mean higher suction pressures and a lower system pressure differential. The compressor can more easily move the refrigerant in a system with a lower pressure differential. This is especially crucial in low-temperature applications. A freezer operating at -20°F can consume 50 percent more energy than a similar freezer operating at 0°F . Setting controls to force refrigeration systems to operate at the lowest possible temperature increases the required system compression ratio and consumes energy needlessly.

18.24 WATER-COOLING EVAPORATORS

Refrigerated liquid coolers can range from small drinking fountains to huge water chillers capable of cooling large buildings. Water-cooling evaporators are made in a variety of sizes and designs. Small units can be of a tube-in-tube coaxial design, as shown in Figure 18-39. A common construction is copper water tube and steel refrigerant tube. Water flows through the inner tube, and refrigerant flows through the outer tube. The tubing is typically twisted or rifled to create turbulent flow. Turbulent flow improves heat transfer by ensuring that all the water passing through touches the surface of the tubing. The water and refrigerant flow in opposite directions. This counterflow design improves efficiency. Coaxial tube in tube evaporators are normally not used for systems above 5 tons in capacity.

Figure 18-39 Coaxial-tube heat exchanger.

Larger chillers use shell-and-tube designs. Both direct-expansion and flooded shell-and-tube chillers are available. The shell in a direct-expansion chiller is filled with water, while the shell in a flooded chiller is filled with liquid refrigerant. The largest chillers usually use flooded evaporators.

SERVICE TIP

It is important that chiller evaporator temperatures stay above freezing to avoid damaging the chiller. It is possible to let the refrigerant pressure and temperature drop below freezing when adding or removing refrigerant from the chiller. Evacuated chillers should be charged with vapor until the vapor pressure in the chiller corresponds to a 36°F saturation temperature. Liquid refrigerant can then be added without freezing the water in the chiller. Liquid refrigerant should be recovered first when a chiller is being evacuated. After all the liquid has been removed, vapor recovery may proceed.

18.25 DRINKING WATER FOUNTAINS

Water fountain evaporators are shell-and-coil evaporators. The evaporator consists of a small storage tank cooled by an external coil of tubing wrapped around the tank and insulated with a Styrofoam cover. This is called double-wall construction, and it is required for potable water for safety. Refrigerant and/or oil would have to pass through both the wall of the refrigerant coil and the water tank to get into the water. Incoming water can be pre-cooled by the cold water draining from the fountain to enhance capacity. Figure 18-40 shows the evaporator on a typical water cooler.

Figure 18-40 The highlighted area shows the evaporator in this water cooler.

Figure 18-41 Roof mounted, air-cooled packaged water chiller.

SERVICE TIP

Anytime you are working around systems that have potable water (drinking water), you must keep the system clean. It is a violation of many local and state health codes to return a system to service that has not been thoroughly sanitized. Refer to the manufacturer’s guidelines on proper system cleanup before putting the system back in service.

18.26 WATER CHILLERS

The most common application for shell-and-tube water chillers is to provide a secondary coolant, namely chilled water. Chilled water is used in air conditioning for cooling multiple remote air-handling units where it would be impractical to run long, multiple refrigerant lines. The chilled water can be pumped wherever required through insulated piping, as shown in the roof-mounted unit in Figure 18-41. The air handlers have water coils instead of direct-expansion refrigerant coils. Water coils are usually several rows deeper than an equivalent direct-expansion coil to get an equivalent cooling performance. They are normally the same size in face area.

Chilled water is also used in process cooling. Many industries have machines that are cooled by water jackets. Chillers are used to remove the heat from the water that is circulated through the machines.

18.27 DIRECT-EXPANSION CHILLERS

In direct-expansion water chillers, the shell is filled with water and refrigerant flows through the tubes. A direct-expansion shell and tube design is shown in Figure 18-42. The

Figure 18-42 Water is in the shell of this direct-expansion chiller; liquid refrigerant flows through the tubes, which are submerged in the water; the refrigerant is superheated before leaving the chiller to prevent any liquid from returning to the compressor.

Figure 18-43 Liquid refrigerant is in the shell of this flooded chiller; the water flows through the tubes that are submerged in the liquid refrigerant; the eliminators prevent any liquid from returning to the compressor.

shell is usually steel, although brass pipe has been used in some smaller diameters. The refrigerant tubes are copper. Some have an integral rolled fin to increase the heat-transfer surface. Some designs utilize metal inserts or turbulators in the tubes to enhance heat transfer on the refrigerant side. The shell holds the water, and baffles provide for even water flow and loading of all circuits. Like all direct-expansion evaporators, the refrigerant is superheated before leaving the chiller.

18.28 CHILLERS—FLOODED

For larger-capacity systems, several hundred tons and up, it is common to use flooded chillers (Figure 18-43), instead of direct-expansion chillers. Flooded chillers also use a shell-and-tube construction. However, the fluids are reversed from the direct-expansion chiller construction. The refrigerant fills the shell and water (or brine) and passes through the tubes. They use enhanced surface tubing for improved refrigerant heat transfer. The tubes are submerged in liquid refrigerant and fill the lower portion of the shell. Refrigerant is controlled by a float valve or orifice, and the shell can act as a surge chamber, permitting separation of refrigerant vapor from liquid. Closely spaced chevron-type eliminator baffles or mesh screens are normally provided to ensure satisfactory separation of dry vapor from liquid. Flooded chillers do not superheat suction vapor and provide very efficient heat transfer.

18.29 CHILLER CAPACITY CONTROL

Controlling the chiller cooling capacity is important. Excess capacity can freeze the water circulating through the chiller. The capacity of the system load is controlled by controlling the water flow. Water flow to small and large cooling coils is controlled by modulating valves controlled by room

Figure 18-44 Packaged brine cooler.

thermostats or other system controls. The chiller capacity can exceed the load when the valves on the water coils start throttling. It is better to avoid starting and stopping the chiller compressor. Instead, the chiller capacity can be reduced by unloading the compressor. Chillers can usually be unloaded down to 25 percent capacity. Beyond that, the water circulating in the system provides a reserve load to be cooled and provides enough cool water permitting satisfactory operation during light load conditions without excessive on/off cycling.

18.30 BRINE COOLERS

Chillers are also used to cool brine. Brine is a solution of salt and water. The saltwater solution can be cooled below 32°F without freezing. Other secondary coolants such as ethylene glycol and propylene glycol and water (antifreeze) are used to make water solutions that can be cooled below 32°F. A brine cooler is shown in Figure 18-44. These are found in skating rink applications and can also be used to produce ice for thermal storage.

Brine often also contains corrosion inhibitors. The same chemical companies that manufacture antifreeze for automobiles manufacture antifreeze for chillers, but the two are not the same. The corrosion inhibitors added to automobile antifreeze are not the same as the inhibitors needed for chiller systems. These chemicals can actually create problems in the water-circulation system.

SERVICE TIP

Check to make sure the antifreeze you intend to use with a chiller is approved for that use. Normally the equipment manufacturer can provide a list of recommended products. Antifreeze solutions will normally identify their intended use on the container.

18.31 SERVICING CHILLERS

When servicing chillers, care should be taken to avoid possible damaging freeze-ups. Water expands when it freezes, destroying the chiller tubes. Chillers normally have flow interlocks that will not let the chiller operate if the water is not flowing. Make sure the flow interlocks are working, so the chiller cannot operate until water flow is established. Check to see that the chilled water thermostat is correctly set. The usual minimum exiting water temperature is about 36°F. Glycol is normally used when chiller temperatures will approach freezing.

Chillers have many safeties, including freeze-stats, low-suction pressure cutouts, and low-refrigerant temperature cutouts. Make certain they are set to the manufacturer's specifications, wired correctly, and operating. Safeties should never be jumped or bypassed.

TECH TIP

A freeze-stat is a thermostat that monitors the chiller water temperature and shuts down the chiller before the water can freeze. Allowing the water in the chiller to freeze can ruin a chiller because the ice expands and ruptures the chiller tubes.

18.32 OVERSIZED EVAPORATOR AND HIGH LOAD

The effect of an oversized evaporator and a system operating with a high load are similar. In both cases there will be more heat entering the refrigerant, and the evaporator temperature will be high. Compressors rely on the returning cool vapor to keep the motor from overheating. A high heat load will cause the compressor to work harder and may cause it to overheat. The temperature of the vapor returning to the compressor will be increased, so it will be less effective in cooling the compressor.

The space temperature will rise, and if the system is on a medium- or low-temperature walk-in, the food product may spoil.

18.33 UNDERSIZED EVAPORATOR AND LOW LOAD

The effect of an undersized evaporator and a system operating with a low load are similar. In both cases there is less heat being transferred to the refrigerant, and the evaporator pressure and temperature will be low. The evaporator pressure and temperature will become lower and lower until a new balance point is reached. There will be little or no superheat, and liquid refrigerant may flood back to the compressor.

If the system is designed for air conditioning, the evaporator temperature can drop below freezing, and the coil will begin to ice up. The formation of ice on the coil can further reduce the temperature, causing more ice to form. If the evaporator temperature drops too low, the compressor can experience an excessively high compression ratio.

Excessively high compression ratios are associated with compressor damage and failure.

Some of the reasons that an evaporator temperature and pressure will drop are listed below. Restricted air flow can be caused by any of the following:

- A dirty evaporator coil
- A dirty air filter
- A bad blower motor
- Ice on the coil

18.34 MISMATCHED EVAPORATOR PERFORMANCE

In the past, many contractors have routinely changed out a condensing unit without changing the existing coil. Typically, the SEER rating of the new condensing unit would be mentioned when the new unit was quoted without informing the customer that the SEER only applies to a matched system. There is no practical way of determining the result from matching a new condenser to an older, unmatched coil that may have been designed for a different SEER condensing unit. The actual performance of these mismatched systems seldom lives up to the rating.

It is important to understand that a system's SEER rating only applies to matched systems. Coils do not have to be manufactured by the same company that manufactured the condensing unit, but they should be tested and listed with that unit as an AHRI match. Just matching components by their nominal rating does not ensure correct operation. AHRI maintains an online directory that allows anyone to check a system match, at www.ahridirectory.org. Certificates verifying the system rating and performance can be printed from this site as well (Figure 18-45).

In January 2006, 13 SEER became the minimum efficiency for new equipment. There is a significant difference in system design between 13 SEER and the previous 10-SEER minimum. If a high-efficiency (SEER) air-conditioning condensing unit is installed and the old evaporator coil is left in service, the coil may be inadequate. The newer units are designed to run at higher evaporating temperatures and need more evaporator coil surface to achieve a satisfactory balance. Also, the older, fixed-orifice metering devices are designed to operate with a higher pressure difference. These metering devices will not operate properly when left installed with newer, higher-efficiency condensing units, as the liquid pressure in these units is lower. Manufacturers recommend changing the evaporator coil when a new high-efficiency unit is installed, to ensure a proper equipment match.

TECH TIP

One major equipment manufacturer installed a new 13-SEER condenser with a new 10-SEER coil and took accurate measurements of the system performance. Using the factory system charge, the system capacity went down and the overall SEER dropped from 10 to 8. Installing a new, higher-efficiency condenser on an old, lower-efficiency coil actually dropped the system efficiency.

UNIT 18—SUMMARY

Evaporators are manufactured for four broad types of application: domestic refrigeration, commercial refrigeration, air conditioning, and chillers. Air-cooling evaporators can be listed by their construction as bare pipe, plate, and tube-and-fin coil. Evaporators may be divided by general operating principle as either direct expansion or flooded. A small percentage of the refrigerant entering a direct-expansion chiller is already gas. The refrigerant leaving a direct-expansion chiller is superheated. The refrigerant entering a flooded chiller is all liquid, and the refrigerant leaving is a saturated gas.

Domestic and commercial refrigeration evaporators may be further listed by their operating temperature: high, medium, and low. The fin spacing on medium-temperature coils is closer together than on low-temperature coils. Most refrigeration evaporators typically operate below freezing and require defrosting. The most common forms of defrost in commercial refrigeration systems are air, electric, and hot-gas defrost. When they are coming out of defrost, the high evaporator temperature can create high pressures, temperatures, and superheat. This is known as hot pull-down.

Air-conditioning evaporators are tube-and-fin type. They may be single-row coils or multi-row coils. Single-row coils produce more sensible cooling and less latent cooling

than multi-row coils do. Air-conditioning coils may be listed by their shape as slab, slant, "A," "N," or "M." By airflow, air-conditioning coils can be upflow, downflow, horizontal, or multi-position. The evaporator pressure and temperature are affected by the return-air wet bulb temperature. High wet bulb temperatures produce high evaporator saturation temperatures. The drain on air-conditioning evaporators should include a trap that is at least 3 in deep to keep negative air pressure from preventing the condensate from draining.

Chillers can be constructed as tube in tube, shell and coil, or shell and tube. Tube-in-tube evaporators are used for small applications up to 5 tons. The water flows in the inner copper tube while the refrigerant flows in the opposite direction through the outer steel tube. Shell-and-coil chillers are used for domestic water coolers. The evaporator is coiled around the outside of the water tank, providing double-wall protection for the potable water in the cooler. Large chillers up to several hundred tons are typically shell-and-tube construction. They may be either direct expansion or flooded. Direct-expansion chillers have the refrigerant in the tubes and the water in the shell, while flooded chillers have the refrigerant in the shell and the water in the tubes.

WORK ORDERS

Service Ticket 1801

Customer Complaint: Poor Cooling and Iced Suction Line

Equipment Type: R-22 Split Air-Conditioning System

A customer has called because her system is not cooling well.

She mentions that there is ice visible on the unit outside. The service technician arrives and sees ice on the suction line and all over the compressor. The customer is surprised that the system can make ice but not cool the house.

The technician explains that ice on an air conditioner does not mean it is working well. In fact, ice is a bad sign in an air-conditioning system. When the technician opens the blower door, the air filter is completely plugged up with dust, and the coil is completely iced over. The technician explains that the dirty filter restricted the airflow over the evaporator, causing its temperature to drop below freezing. Once the ice started forming, it also caused airflow restriction. Liquid refrigerant then slowly worked its way down the suction line to the compressor.

The technician turns system off and turns the fan to ON to melt the ice. This way, the ice melts slowly enough for the drain pan to handle the water. When the ice is clear, the technician restarts the system with a clean air filter and measures the airflow. After determining that the airflow is correct, the system pressure, superheat, and subcooling are all checked. The system is operating

within the manufacturer's specifications with the correct airflow.

Service Ticket 1802

Customer Complaint: Chiller Not Working

Equipment Type: R-134a Flooded Chiller Used for Process Cooling

A customer calls to say that his process chiller is not working. Occasionally the plant maintenance crew had found the chiller off on the freeze-stat. When they pushed it, the chiller would work for a while until it went off again on the freeze-stat. Eventually, they jumped out the freeze-stat to keep the chiller operating. This worked for about a day, but now it does not work at all. The technician checks system refrigerant pressure and notices that the pressure is very low. Suspecting ruptured chiller tubes, the technician drains some water from the chiller loop and notices that it is murky and oily. The chiller is drained, the tubes are pressure tested, and the rupture is confirmed.

The technician explains that the freeze-stat was probably tripping because the exiting water temperature was getting too close to freezing. The freeze-stat tripping was not the problem but a symptom. Jumping the safety only forced the chiller to operate at a dangerous condition, freezing the water in the chiller and rupturing the tubes. The chiller has been ruined. The technician warns that the original problem may still exist if something in the water loop outside the chiller was causing low water flow.

Service Ticket 1803

Customer Complaint: Poor Cooling and High Electric Bills

Equipment Type: R-22 Split System with New Condenser and Old Evaporator

A customer calls a company to look at a new air-conditioning unit that is not cooling properly. The unit was installed by the customer's brother-in-law while he was visiting from out of state. The compressor in the old system died and the brother-in-law changed out the entire condensing unit with a new 13-SEER model. The new condensing unit was connected to the twenty-year-old capillary-tube evaporator coil. The technician checks the system airflow and refrigerant pressures. The airflow is normal, but both pressures are low and the superheat is high. The technician suspects that the condenser and coil are not an AHRI match. A quick check of the AHRI online directory confirms that the system is not an approved match. The technician explains to the customer that the problem is that condenser and evaporator are not matched and suggests that the customer have a matched coil installed.

Service Ticket 1804**Customer Complaint: Water Leaking on Ceiling Under Unit****Equipment Type: R-410a Heat Pump with the Blower Coil Installed in the Attic**

A customer has called about water leaking on the ceiling under a heat pump blower coil in a new house. The technician notices that the blower coil is installed directly on the ceiling joists with no secondary drain pan. There is very little fall in the condensate line, which also runs across the ceiling joists until it exits. Further, there is no trap in the condensate line. Water is dripping out from the cracks in the bottom panels, and the ceiling insulation under the unit is wet. The technician informs the customer that the blower coil should be elevated about 6 in so that a 3-in trap can be installed in the drain and the drain can slope toward the exit point. The technician also points out that a secondary drain pan should be installed under the unit to avoid similar problems in the future.

Service Ticket 1805**Customer Complaint: Compressor Shutting off on Overload After Defrost Cycle Is Completed****Equipment Type: R-404a Open-Display Commercial Refrigeration Freezer**

The compressor on a new frozen food open display case sometimes shuts off on overload when it starts after the completion of a defrost cycle. The technician monitors the case operation during the cooling cycle and finds the pressures, temperatures, and current draws to be within the manufacturer's specifications. The case goes into defrost and defrosts successfully. When the case comes out of defrost, the suction pressure and compressor amp draw are both high. After running a few minutes at the elevated temperatures and pressures, the compressor overload opens and the compressor shuts down. The technician waits for the overload to cool and reset and then restarts the compressor. This time the technician throttles the suction pressure to the compressor by running the suction service valve toward the front seat position and watching the compressor amp draw. The compressor continues operating. As the coil temperature drops, the suction pressure and amp draw also drop. After fifteen minutes the compressor operates normally without throttling.

The technician explains to the customer that the compressor amp draw is too high on restart after defrost because it is trying to pull down the hot evaporator coil and is being overloaded. The technician explains that this can be remedied by installing a crank case pressure regulator, which will prevent the returning pressure from exceeding the maximum safe operating pressure for the system.

UNIT 19

Refrigerants and Their Properties

OBJECTIVES

After completing this unit, you will be able to:

1. define *refrigerant*.
2. identify the type of refrigerant by its number designation.
3. list the different types of refrigerant chemical composition.
4. explain the difference between compounds, zeotropes, and azeotropes.
5. describe the pressure-temperature relationship of saturated refrigerant.
6. list the different types of refrigerant contaminants.
7. explain the refrigerant safety rating system.
8. match refrigerants with the proper refrigeration oil.

19.1 INTRODUCTION

Any study of the refrigeration cycle would be incomplete without a look at the refrigerant in the system. The refrigerant is the first component of a refrigeration system that must be determined, since its chemical and physical properties will play a large role in selecting all other components in a refrigeration system. A number of materials have physical and thermodynamic properties that make them suitable for use as refrigerants. In fact, anything that can boil at a low temperature and condense at a higher temperature can be used as a refrigerant. Water can even be used as a refrigerant under the right conditions. Although water boils at 212°F at standard atmospheric pressure, it boils at 40°F in a vacuum of 29.75 in Hg (Figure 19-1).

19.2 DEFINITION OF A REFRIGERANT

Refrigerant is the fluid used in a refrigeration system for transferring heat. Gases or liquids can do this by increasing in temperature. Cooling operations that depend on a temperature change in the refrigerant use the sensible heat properties of the refrigerant. However, the effectiveness of this approach is limited to the specific heat capabilities of the refrigerant and the volume of refrigerant that can be moved. Refrigeration processes that depend only on sensible cooling must move large amounts of refrigerant.

A much larger amount of heat can be absorbed and transferred when a liquid is vaporized to a gas. This method takes advantage of the latent heat characteristics of the refrigerant and results in much higher operating efficiency due to the reduced quantity of refrigerant that must be circulated. Refrigerants in mechanical refrigeration systems do this by changing their physical state. They absorb heat by evaporating from a liquid to a vapor; they release heat by condensing from a vapor back to a liquid. The refrigerant's temperature is controlled by its pressure. Lower pressures yield lower temperatures, while higher pressures yield higher temperatures.

TECH TIP

A comparison between the specific and latent heat properties of R-134a can illustrate how much more heat can be absorbed through changes in state. The specific heat of R-134a vapor is 0.19 BTU/lb. A pound of vapor can only absorb 19 BTU while changing in temperature 100°F. Fifty-three pounds of R-134a would have to be circulated to absorb 1,000 BTU, even if the refrigerant were to rise 100°F in temperature (1,000/0.19). Even more refrigerant, 530 lb, would be required if the refrigerant were to rise in temperature only 10°F. By comparison, the latent heat of vaporization of R-134a is 92.8 BTU/lb. Only 11 lb are required to absorb the same 1,000 BTU by boiling from a liquid to a vapor.

Figure 19-1 Pressure-temperature curve for water.

19.3 TEMPERATURE-PRESSURE RELATIONSHIPS

The pressure inside a refrigerant cylinder, or inside a system, is created by vapor. If all the vapor inside a closed cylinder condenses, there is no pressure. The boiling temperature of any liquid is controlled by the vapor pressure exerted on the liquid. The pressure and temperature of any saturated liquid tend to go up and down together. If you know one, you can find the other.

Charts called pressure-temperature charts, or PT charts for short, are commonly used in refrigeration. These charts correlate the saturation temperature and pressure of commonly used refrigerants (Figure 19-2). The vapor pressure of most common refrigerants can be found by consulting a PT chart. If the temperature of a saturated refrigerant can be determined, its pressure can be determined. Most of these charts list temperature in a column on the left-hand side of the chart. To use the chart, find the saturation temperature in the left-hand column and follow across that same row until reaching the column of the refrigerant being used. That gives the pressure of that refrigerant corresponding to that

particular saturation temperature. In Figure 19-3, at a temperature of 40°F, saturated R-134a will have a pressure of 35 psig. Of course the chart can also be used the other way. Find the pressure in the column under the refrigerant being used and then follow across that same row to the temperature column on the outside. This gives the saturation temperature of the refrigerant at that particular pressure. In Figure 19-4, saturated R-22 with a pressure of 43 psig will have a temperature of 20°F.

There is an important point that must be remembered: these charts are specifically designed for saturated refrigerant only. They do not work with superheated gas or subcooled liquid. To be saturated, the refrigerant must be ready to evaporate or condense. In practical terms, saturated refrigerant is usually a mixture of liquid and vapor, not all vapor or all liquid. It is true that PT charts are used to calculate superheat and subcooling, but PT charts cannot be used to predict the pressure or temperature of a superheated gas or a subcooled liquid. Rather, superheat and subcooling are calculated by comparing the saturation temperature on the PT chart to the actual refrigerant temperature.

Saturated PT charts are very useful for determining the actual evaporating and condensing temperatures of the refrigerant in the system. Generally, the PT charts will yield a much more accurate evaporating or condensing temperature than attempts to measure them directly with a thermometer. For example, an R-410a system operating at pressures of 118 psig on the low side and 365 psig on the high side would have an evaporator saturation temperature of 40°F and a condenser saturation temperature of 110°F (Figure 19-5).

19.4 REFRIGERANT CLASSIFICATION

Refrigerants have many physical and chemical characteristics that determine their suitability for any particular system. There are many groupings of refrigerants based on these characteristics, with the most common characteristics as follows:

- Operating pressure
- Chemical composition
- Formulation
- Toxicity
- Flammability
- Ozone-depletion potential
- Global-warming potential

19.5 OPERATING PRESSURE

The EPA regulations for preventing the release of ozone-depleting substances divide refrigerants into three categories of operating pressures: low pressure, high pressure, and very high pressure. The recovery methods and levels specified for each refrigerant depend upon the refrigerant's operating pressure range. The operating pressure range is determined by the boiling point of the refrigerant at atmospheric pressure. Low-pressure refrigerants have a boiling point at atmospheric pressure above 10°C (50°F). High-pressure refrigerants have a boiling point at atmospheric pressure between −50°C (−58°F) and 10°C (50°F). Very-high-pressure refrigerants have a boiling point at atmospheric pressure below −50°C (−58°F). Generally speaking, the lower the refrigerant's operating pressure, the higher the evaporator saturation temperature. Systems using low-pressure refrigerant typically have an evaporator saturation temperature of 40°F or higher. Systems using very-high-pressure refrigerant typically have evaporator saturation temperatures of −40°F and lower. High-pressure refrigerants are used in the widest variety of applications. Systems using high-pressure refrigerant may have an evaporator saturation temperature between −20°F and 50°F. Figure 19-6 shows examples of refrigerants according to their operating pressure range.

Operating Pressure	Refrigerants
Low pressure	R-11, R-123
High pressure	R-12, R-22, R-134, R-502, R-507
Very high pressure	R-503, R-410A

19.6 REFRIGERANT CHEMISTRY

Refrigerants can be divided into five major chemical categories based on their chemical composition:

- Hydrocarbons
- Chlorofluorocarbons
- Hydrofluorocarbons
- Hydrochlorofluorocarbons
- Natural refrigerants

Refrigerants are now frequently referred to by their chemical family using the first letters of each chemical component in the refrigerant to produce abbreviations (HC, CFC, etc.). Common refrigerant chemical families are shown in Figure 19-7.

Compounds

Until recently, most refrigerants were compounds. Water is a good example of a compound. Take a highly flammable gas, hydrogen, combine it chemically with oxygen, a gas that is necessary for combustion, and the result is water, a chemical that does not burn and is widely used to extinguish flames. Two chemicals have been combined to make a new chemical with distinct chemical properties that are completely separate from the properties of the original chemicals. Further, these chemicals cannot be separated by physical means. The hydrogen cannot be distilled from the oxygen by boiling the water. Any pure chemical or compound has a specific saturation temperature for any given pressure. The boiling temperature can be precisely determined if the pressure on the liquid is known. Examples of refrigerants that are compounds include some of the old standards: R-11, R-12, and R-22. These are all based on the same molecule, methane (Figure 19-8).

19.7 HC REFRIGERANTS

Hydrocarbons are compounds consisting of carbon atoms tied to each other in chains surrounded by hydrogen atoms. Figure 19-9 shows the arrangement of hydrogen and

carbon atoms in several common hydrocarbons. Normally, hydrocarbons are thought of as fuels; they are burned for energy. Hydrocarbons make excellent refrigerants. In addition to being excellent refrigerants, they are environmentally friendly. Hydrocarbons have zero ozone depletion because they contain no chlorine or bromine, and their global-warming potential is very low compared to halogenated refrigerants. Unfortunately, hydrocarbons are not just flammable but explosive. Hydrocarbons are only approved for limited applications in the United States. They are more widely used in other places, including Australia, Canada, China, and Europe. Hydrocarbons are sometimes used in small quantities in zeotropic blends to help with oil return. The amount of hydrocarbons used in these blends is so low that the mixture retains a nonflammable safety rating. Figure 19-10 shows a list of common hydrocarbon compounds and their refrigerant number.

19.8 HALOGENATED REFRIGERANTS

All halogenated refrigerants are based on hydrocarbons, like methane. Halogenated refrigerants are formed by combining a hydrocarbon with halogens. Halogens are a group of five highly reactive chemicals:

- Chlorine
- Fluorine
- Bromine
- Iodine
- Astatine

Chlorine and fluorine are the primary halogens used to make halogenated refrigerants. The halogens replace hydrogen atoms in the hydrocarbon molecules. If only some of the hydrogen atoms are replaced, the refrigerant is partially halogenated. If all of the hydrogen atoms are replaced, the refrigerant is fully halogenated. Fully halogenated CFC refrigerants are more chemically stable than partially halogenated HCFC and HFC refrigerants. Partially halogenated HCFC and HFC refrigerants can be more easily broken down because of the presence of hydrogen. Some advantages of halogenated refrigerants are that they are generally nonflammable, low in toxicity, and do not chemically react with many materials. This is primarily because they are very chemically stable molecules. The chlorine in halogenated refrigerants and the bromine in halon fire suppressant are the halogens responsible for ozone depletion. Chemicals that contain either chlorine or bromine contribute to ozone depletion.

19.9 CFC REFRIGERANTS

CFC is short for *chlorofluorocarbon*. CFC refrigerants contain chlorine, fluorine, and carbon. They are fully halogenated refrigerants with chlorine and fluorine replacing all the

**Figure 19-11** CFC-12 is based on the methane molecule.

hydrogen atoms of a hydrocarbon compound. Most CFC refrigerants are built around the methane or ethane molecules. Figure 19-11 shows the chemical structure of R-12, which is built on a methane molecule.

CFC refrigerants were once the most common type of refrigerants in use. However, CFC refrigerants are the worst offenders in terms of ozone depletion; they have the highest ozone-depletion potentials of any group of refrigerants. CFCs also have a relatively high global-warming index and a long atmospheric lifetime. CFCs make good refrigerants because they are very chemically stable. This stability is also what makes them an environmental liability. CFCs do not break down in lower earth atmosphere. They find their way up to the stratosphere, where the high-intensity ultraviolet light breaks the CFCs apart, releasing the chlorine in the stratosphere.

It has been illegal to intentionally vent CFC refrigerants into the atmosphere since July 1, 1992, and 1995 was the last year that CFCs were allowed to be manufactured or imported into the United States, so the supply of CFCs is very low. Some CFC refrigerant is still available at very high prices, but there is now very little demand. Figure 19-12 lists some of the most common CFC refrigerants.

19.10 HCFC REFRIGERANTS

HCFC is short for *hydrochlorofluorocarbon*. HCFCs contain hydrogen, chlorine, fluorine, and carbon. Most HCFC refrigerants are built around the methane or ethane molecules. Figure 19-13 shows the chemical structure of R-22, which is built on a methane molecule.

HCFCs are only partially halogenated because they still have some hydrogen atoms. This makes them less stable than CFC refrigerants and more environmentally friendly.

Figure 19-12 CFC refrigerants.

Figure 19-13 HCFC-22 is based on the methane molecule.

HCFCs still have an ozone-depletion potential because they still have chlorine. Their ozone-depletion potential is far less than the ozone-depletion potential of CFC refrigerants because HCFCs are more likely to break down in the lower atmosphere. Once the chlorine is released in the lower atmosphere it finds plenty of chemicals to attack, so it will not reach the stratosphere.

The most common HCFC refrigerant is R-22. Since January 1, 2010, new equipment charged with R-22 cannot be manufactured or imported, and R-22 is scheduled for a total phaseout on January 1, 2020. All HCFC refrigerants are scheduled to be phased out on January 1, 2030. R-22 has been the least expensive halogenated refrigerant available, but the price of R-22 is rising quickly because its production has been cut back. Figure 19-14 lists some of the most common HCFC refrigerants.

19.11 HFC REFRIGERANTS

HFC is short for *hydrofluorocarbon*. HFCs contain hydrogen, fluorine, and carbon. Most HFC refrigerants are built around the ethane molecule. Figure 19-15 shows the chemical structure of R-134a, which is built on an ethane molecule.

HFC refrigerants are only partially halogenated because they still have some hydrogen atoms. This makes them less stable than CFC refrigerants. They are more environmentally friendly than either CFC or HCFC refrigerants because they contain no chlorine and therefore have no ozone-depletion potential. However, HFC refrigerants do still have a global-warming potential. It has been illegal to intentionally vent HFC refrigerants into the atmosphere since November 15, 1995. Figure 19-16 lists some of the most common HFC refrigerants.

19.12 CO₂ REFRIGERANT

Interest in using CO₂ as a refrigerant has been increasing because it is nontoxic and nonflammable, does not deplete the ozone layer, has a very low global-warming potential, and is inexpensive. The biggest challenge is the extremely

high pressures necessary for CO₂ systems to operate. A pressure of over 1,400 psig is necessary for an air-cooled system similar to a common refrigeration system. CO₂ will not condense at temperatures above 88°F because the temperature and pressure in the high side exceed the critical point. Heat is rejected by sensible cooling of the gas. These CO₂ systems are called transcritical systems because they operate both above and below the critical point. The high side of a transcritical system operates above the critical point, and the low side operates below the critical point. CO₂ can also be applied as the low-temperature portion of a cascade system, where the CO₂ condenser is cooled by the evaporator of another refrigeration system that uses a more traditional refrigerant. By keeping the condenser at a low temperature, the CO₂ system operates like a “normal” refrigeration system, below the critical point.

19.13 FORMULATION

All refrigerants are combinations of two or more chemicals, but there are differences in how these chemicals are combined. The chemicals used to form a refrigerant can be combined in one of three ways:

- Compounds
- Zeotropes
- Azeotropes

TECH TIP

The terms *zeotropic* and *azeotropic* derive from Greek. *Zeo* means “to boil,” and *trope* means “to turn.” Thus, zeotropic refrigerants turn, or change, as they boil. The mixture changes (trope) as it boils (zeo). The prefix *A-* means “not.” Placing the prefix *A* in front of a word effectively turns the word upside down. For example, an amoral person is one who does not have morals. An azeotropic refrigerant does not change as it boils.

19.14 ZEOTROPES

One result of the demise of CFC refrigerants has been the proliferation of refrigerant mixtures. Unlike compounds, these are combinations of chemicals that do not form a new

Figure 19-17 R-410A is an example of a zeotropic refrigerant.

chemical and whose physical properties are a sort of blending of the physical properties of the individual components. Zeotropic refrigerants change in percentage mixture as they change state. A more common term that is widely used for zeotropic refrigerants is *blends*. Sometimes the number of components in the blend is mentioned. Ternary blends are mixtures of three refrigerants, while binary blends are made up of two refrigerants. All refrigerants whose number is in the 400 series are zeotropes (Figure 19-17).

The behavior of a zeotropic refrigerant can be compared to a mixture of alcohol and water. The alcohol can be separated from the water through distillation. The alcohol tends to boil before the water, leaving more water and less alcohol in the remaining liquid. The boiling point of the mixture changes as the percentage of the two components in the mixture changes. The mixture changes as it boils.

From the standpoint of refrigeration, this change in composition is significant because the boiling temperature of the remaining liquid also changes as the mixture percentage changes. This is not like a normal refrigerant that maintains a fixed boiling temperature for any particular pressure. Zeotropic refrigerants will boil within a range of temperatures for any given pressure.

Bubble Point and Dew Point

When heating a saturated liquid mixture, the temperature at which small vapor bubbles first begin to form is known as the bubble point. Coming the other way, the temperature at which small liquid droplets first start to form when cooling

a saturated vapor is known as the dew point. In compounds these two points are the same for any pressure. With zeotropes, however, the dew point is typically a higher temperature than the bubble point at any particular pressure. The difference between these two temperatures is known as glide. For example, the bubble point and dew point for R-12 at a pressure of 28 psig is 30°F. For R-401a, an R-12 substitute, the bubble point is 20°F and the dew point is 30°F at 28 psig. So while an evaporator with R-12 will always be 30°F when boiling at 28 psig, the evaporator temperature of an R-401a system can be anywhere between 20°F and 30°F at the same 28 psig saturation pressure.

Not all zeotropic blends have such a large glide. For example, the dew point and bubble point for R-410a are typically within 1°F. In fact, most PT charts do not even bother listing both the dew point and bubble point for R-410a.

TECH TIP

Many confusing names have been coined in a marketing effort to distinguish between high-glide zeotropes, like 401a, and low-glide zeotropes, like 410a. Low-glide zeotropes have been referred to as NARMS (for “nearly azeotropic refrigerant mixtures”), “near azeotropic blends,” or, worst of all, “azeotropic mixtures.” If you de-Greek the word *azeotropic* it means “does not change while boiling.” Saying something “nearly does not change when it boils” really makes no sense. Even more confusing is the term *azeotropic mixture*. Since azeotropes are mixtures by definition, this term really confuses the issue. A few simple rules will keep the difference between zeotropes and azeotropes clear. If the refrigerant number is in the 400 series, it is a zeotrope. If the refrigerant must be removed from the cylinder as a liquid, it is a zeotrope. Azeotropes have numbers in the 500 series and may be removed from the cylinder as either a vapor or a liquid.

Pressure-Temperature Charts for Zeotropes

Simple PT charts work for pure compounds, like R-134a, but they do not work for zeotropic refrigerants since the boiling point shifts some as they boil. Therefore, charts for high-glide blends include two temperatures for each pressure: a dew point and a bubble point (Figure 19-18). Low-glide zeotropes like R-410a are commonly still listed as a single point because the difference between the bubble point and the dew point is typically less than 1°F.

Fractionation

The separation of the components in a zeotropic blend is called fractionation. The refrigerant is essentially being distilled by removing a fraction of its mixture. Zeotropic refrigerants should only be removed from the cylinder as a liquid to avoid fractionation.

Fractionation can also occur due to a leak, with one component leaking out at a faster rate than the other components. Fractionation is more likely if the leak is in the

evaporator or condenser, because fractionation occurs during a change of state. Because of this possibility, early advice for recharging systems using zeotropic refrigerants was to recover the remaining system charge and recharge the system with new refrigerant. This was based on the assumption that the refrigerant would fractionate as it leaked out. Practical experience has shown that concerns about fractionation due to leaks are largely unfounded. However, the absolute best way to charge a system that uses a zeotropic refrigerant is to recover the remaining refrigerant and recharge the system with a full charge of new refrigerant. Most manufacturers making systems that use low-glide blends now state that it is acceptable to top off a system charge without recovering the residual system refrigerant.

Handling Zeotropes

The primary difference between handling zeotropes and other refrigerants is how the refrigerant is removed from the cylinder. The instructions for working with zeotropic refrigerants are typically on the refrigerant cylinder (Figure 19-19). All zeotropes are handled the same way: they must leave the cylinder as a liquid to stay mixed in the correct ratio. If vapor is taken out of the cylinder, the liquid will boil to replace the vapor being removed. This causes a separation of the components in the mixture. Not only will the gas going into the system be the wrong mix, but all the remaining liquid left in the cylinder is ruined as well! Remember that all 400 series refrigerants are zeotropes and must leave the cylinder as a liquid.

SERVICE TIP

Some cylinders contain dip tubes so that liquid comes out of the valve on top of the cylinder when the cylinder is in the upright position. Other cylinders do not have the dip tube. How do you know which is which? Read the instructions. The cylinders have arrows painted on them to inform technicians exactly how to use the product.

19.15 AZEOTROPES

Occasionally some binary mixtures of refrigerants will have one specific mixture ratio where the bubble point and dew point temperatures are the same. In short, the mixture behaves like a compound. These mixtures cannot be physically separated since the components are evaporating in the same ratio as the mixture. These are called azeotropic refrigerants, for “not” zeotropic, because they do not change their boiling point as they boil. Azeotropic refrigerants are still mixtures because they are not chemically bonded, but they cannot be separated physically. For example, R-507 is 50 percent R-125 and 50 percent 143a. When R-507 boils, the R-125 and the R-143a boil in the same 50/50 ratio. It is not possible to separate the two original refrigerants by boiling the mixture. Azeotropes can be handled just like compounds, or “pure” refrigerants, since they will not separate when they change state. All azeotropes have a 500 series number.

19.16 SAFETY

ASHRAE Standard 34, Safety Code for Mechanical Refrigeration, addresses refrigerant safety. Refrigerants are grouped by their toxicity and flammability. Each refrigerant is assigned a safety rating consisting of a letter and a number. Letter A identifies refrigerants with lower toxicity, and letter B identifies refrigerants with higher toxicity. A number indicating the flammability of the refrigerant follows the letter. The lower the number, the lower the flammability.

Toxicity

Almost anything can be toxic in high enough concentrations. For example, the air we breathe is approximately 78 percent nitrogen. However, breathing 100 percent nitrogen will cause asphyxiation. The maximum safe exposure level in parts per million is called the threshold limit value (TLV). The TLV is not for a one-time exposure but is based on an exposure for an eight-hour day, forty-hour week. A refrigerant’s TLV is used to rate its toxicity level. A is used to designate low-toxicity refrigerants having a TLV of 400 or more. B designates high-toxicity refrigerants having a TLV less than 400. Type B refrigerants are prohibited in many applications by building and safety codes.

Most common CFC, HCFC, and HFC refrigerants are listed as type A refrigerants. One notable exception is R-123. R-123 is a low-pressure HCFC refrigerant that is used in large, low-pressure chillers. It is considered a type B refrigerant. Many older refrigerants are type B, including ammonia, sulfur dioxide, and methyl chloride. Note that this rating system does not distinguish between refrigerants like these that will kill you in a few minutes from refrigerants like HCFC-123, which will cause some physical distress when you are exposed for eight hours a day, forty hours a week.

Flammability

A refrigerant’s flammability is listed as type 1, nonflammable; type 2L, lower flammability with a maximum burning velocity less than 10 cm/s; type 2, lower flammability; or type 3, higher flammability. Nonflammable refrigerants will not ignite and will not support combustion. Refrigerants

listed as type 2L or 2 will ignite when exposed to a flame but will not continue to burn when the flame is removed. Refrigerants with a type 2 flammability rating do not have a flash point; they will not explode. Refrigerants with a flammability rating of 3 will ignite, they will support combustion, and they do have a flash point. R-12 is an example of a refrigerant with a flammability rating of 1. HFO 1234yf is an example of a refrigerant with a 2L flammability; ammonia, R-717, is an example of a flammability 2 refrigerant; and propane, R-290, is an example of a flammability 3 rating.

Combined Rating

A refrigerant's safety rating is a combination of the toxicity letter and the flammability number. A refrigerant that is nontoxic and nonflammable would have an A1 rating. A refrigerant that is toxic and very flammable would have a B3 rating. Figure 19-20 shows the combined ratings for several refrigerants.

Safety Rating for Zeotropes

Zeotropic refrigerants can fractionate when they boil. This raises the possibility that a mixture's characteristics can change. For this reason, zeotropic refrigerants are assigned

a dual rating. The first rating is for the characteristics of the original mixture; the second rating is for the characteristics in a worst-case fractionation. For example, a zeotropic refrigerant could have a rating of A1/A2. This would mean that the original mixture would be nonflammable and nontoxic but that the result of a worst-case fractionation would be nontoxic and somewhat flammable. Most commonly used zeotropic refrigerants have a safety rating of A1/A1, but there are a few with a rating of A1/A2. This indicates that the mixture can be ignited if the refrigerant has been fractionated. Azeotropic refrigerants are rated just like pure compounds because they do not separate when they boil.

Chemical Interactions

There are safety concerns that arise from the interaction of refrigerants and their surroundings. For example, CFCs and HCFCs are not flammable. However, they chemically decompose when exposed to flames or very high temperatures, releasing their chlorine and fluorine. This creates highly irritating and potentially toxic gases, including chlorine gas, fluorine gas, and phosgene gas. HCFCs and HFCs can react violently with some metals. HCFCs should never be exposed to magnesium. HFCs should not be allowed to come into contact with freshly abraded aluminum.

Figure 19-20 Refrigerant safety classification.

Aluminum that has been recently ground up can react violently with HFCs. Some HFCs are flammable under high pressure with large concentrations of oxygen. Of course you should never put oxygen or compressed air into any refrigeration system. The oxygen under pressure can cause an explosion when mixed with the refrigerant oil.

Asphyxiation

Most refrigerants are heavier than air and will displace the air in a room. Releasing large quantities of nontoxic refrigerant into a confined space can cause asphyxiation. This can sneak up on technicians because the refrigerant does not attack the body. Nobody would hang around long enough to asphyxiate from a large release of ammonia; if you are able to leave, you will. On the other hand, R-22 does not attack the body. Victims just get lightheaded from lack of oxygen. This can be very dangerous in confined spaces. So not only will preventing large releases of CFCs help preserve the ozone layer, but it helps preserve technicians as well! In the event of a large release of refrigerant, leave! Ventilation, particularly in low-lying places, will help clear the room. The mechanical room for large systems containing a class B refrigerant should have a self-contained breathing apparatus. However, the best course of action is to get out of the room.

Frostbite

Of course, all refrigerants can be cold. Letting liquid refrigerant come into contact with exposed skin can cause "burns." Immediately after the incident, the skin will just look irritated and red. In one hour after the exposure, blisters will start to appear and the skin will start to swell and puff up. In bad cases, the outer skin comes off and the area is treated like a third-degree burn. Technicians should wear safety goggles to protect their eyes and neoprene-lined gloves to protect their hands when handling refrigerants.

SAFETY TIP

HFC-410 boils at -62°F at atmospheric pressure. Skin exposed to a direct liquid stream for only a minute can receive severe frostbite that acts like a second- or third-degree burn. Keep your hands out of streams of liquid refrigerant. Refrigerant can be replaced, but your hands cannot!

19.17 OZONE DEPLETION

M. J. Molina and F. S. Rowland published a laboratory study in 1974 demonstrating the ability of CFCs to break down ozone in the presence of ultraviolet light. Observations of the ozone layer have since demonstrated that the concentration of ozone in the stratosphere is decreasing. The most severe ozone loss was discovered over Antarctica. The loss of ozone over Antarctica is referred to as the "ozone hole." Many people once believed that ozone depletion could only occur at the poles, but reductions in ozone have also been observed in northern middle latitudes.

Ozone Layer

Scientists studying the earth's atmosphere generally divide it into six regions: troposphere, stratosphere, mesosphere, thermosphere, exosphere, and ionosphere (Figure 19-21). The troposphere extends from the earth's surface to about 6 miles above the earth. The stratosphere starts at 6 miles above the earth and extends to 30 miles above the earth. The ozone layer is really just a concentration of ozone molecules within the stratosphere (Figure 19-22). Ozone is a form of oxygen.

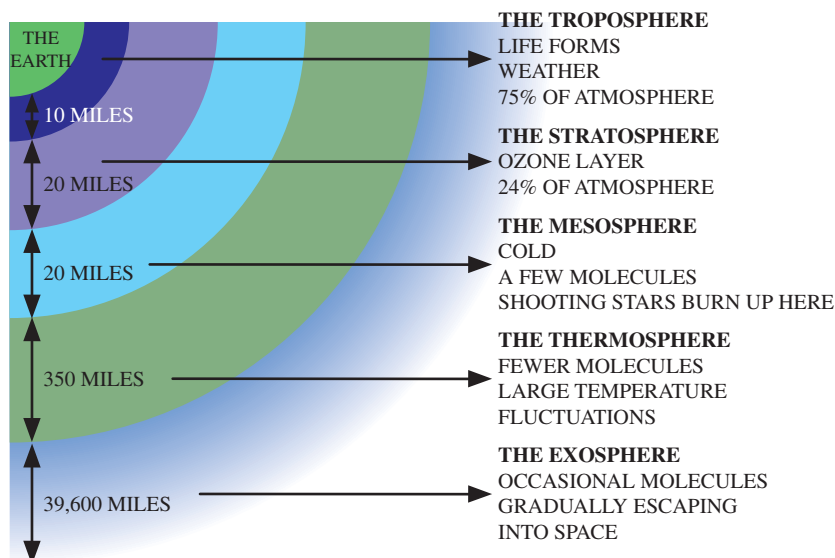

Figure 19-21 Layers of the earth's atmosphere.

Figure 19-22 The ozone layer is inside the stratosphere. (NASA)

Figure 19-23 Ozone molecules are composed of three oxygen atoms, while the standard oxygen molecule is composed of two oxygen atoms.

The oxygen we breathe, O_2 , is formed from two oxygen atoms. Ozone molecules are formed from three oxygen atoms, O_3 . Figure 19-23 shows normal O_2 and ozone, O_3 . Ozone is a relatively unstable molecule that normally has a short lifetime. Ozone is constantly produced and destroyed in a natural cycle. However, the overall amount of ozone has remained essentially stable as a result of a natural balance between ozone creation and destruction. Large increases in stratospheric chlorine and bromine have upset that balance by adding to the destruction side of the equation.

Ozone-Depletion Chemistry

The ozone-depletion process begins when ozone-depleting substances, including CFCs and HCFCs, are released into the atmosphere. Winds efficiently mix all the different gases in the part of the atmosphere closest to earth, the troposphere. CFCs are extremely stable and do not break down in the atmosphere. After a period of several years, CFC molecules reach the stratosphere, the atmospheric layer above the troposphere. Strong ultraviolet light breaks apart the CFC and HCFC molecules. CFCs and HCFCs release chlorine atoms when they are broken apart. It is these chlorine atoms that actually destroy ozone, not the intact CFC or HCFC molecules. The free chlorine pulls an oxygen atom off of the O_3 ozone molecule to form O_2 and chlorine monoxide, ClO . Chlorine monoxide then pulls an oxygen atom off of another O_3 ozone molecule to form two O_2 molecules, and once again the chlorine is free. It is estimated that one chlorine atom can destroy over 100,000 ozone molecules before it is removed from the stratosphere. Figure 19-24 illustrates this process.

Since ozone filters out harmful ultraviolet B (UVB) radiation, less ozone means higher UVB levels on the ground. UVB has been linked to skin cancer, cataracts, and harm to certain crops and marine organisms. Although some UVB reaches the surface even without ozone depletion, the harmful effects of UVB will increase as the concentration of stratospheric ozone decreases.

Figure 19-24 Stages of ozone depletion caused by a CFC = 12 molecule.

Figure 19-25 Classes of ozone-depleting substances.

Refrigerant Class	Ozone Depletion Potential	Refrigerants
Class I	ODP > 0.2	CFC-11, CFC-12, R-500, R-502
Class II	ODP < 0.2	HCFC-22, HCFC-123

Ozone-Depletion Potential

Ozone-depletion potential, ODP, compares a refrigerant’s ozone-depleting effect to R-11. By definition, the ODP of R-11 is 1. The ODP of most refrigerants is less than 1, but there are other substances, such as halons, with ODPs much greater than 1. Note that refrigerants that do not contribute to ozone depletion are not classified in this system. The EPA divides ozone-depleting refrigerants into two classes based on their ozone-depletion potential.

- **Class I** refrigerants have an ODP greater than 0.2.
- **Class II** refrigerants have an ODP less than 0.2.

This classification is becoming a historical artifact because nearly all Class I refrigerants are CFCs, and CFC production and importation have been banned since the end of 1995. It is still possible to purchase CFC refrigerants from a supplier who still has refrigerant left over from 1995, or from a refrigerant reclaimer. Class II refrigerants will be around for some time to come, but their time is also limited. HCFC refrigerants are scheduled to be phased out completely by 2030. Figure 19-25 shows refrigerant classes according to their ozone-depletion potential.

19.18 GLOBAL WARMING

Global warming is the gradual rise in the earth’s temperature because of an increase in greenhouse gases. The glass in greenhouse works by allowing most wavelengths of light energy in and blocking the escape of infrared energy. Visible light has short wavelengths and can penetrate the glass. The light strikes surfaces and some of the visible light energy is converted into heat energy. The longer-wavelength infrared waves cannot penetrate the glass. This has the effect of trapping in heat. Some gases in the earth’s atmosphere behave like the glass in a greenhouse, trapping heat in (Figure 19-26). These gases are referred to as greenhouse gases. This is actually important to our survival. Without the greenhouse effect, temperatures would be quite chilly, especially at night. The problem is that greenhouse gases in the atmosphere have increased to the point that the earth’s atmosphere has become warmer. The primary global-warming gas is carbon dioxide, CO₂. CO₂ is assigned a global-warming potential, GWP, of 1. Other gases are compared to CO₂ to arrive at their GWP.

The GWP of a refrigerant takes into account both its direct effect on global warming and its indirect effect. Its indirect effect includes its interaction with other gases and its effect on energy use. All GWP values shown are calculated over a 100-year time horizon. All halogenated refrigerants contribute to global warming. In fact, the GWP of

Figure 19-26 Illustration of the greenhouse effect and global warming. (NASA)

HFCs is generally worse than for the HCFCs they replace. Figure 19-27 shows the relative ozone-depletion and global-warming potential for several common refrigerants.

CODE TIP

On December 7, 2009, the EPA declared that the current and projected atmospheric concentrations of the six key, well-mixed greenhouse gasses, including HFCs, “threaten the public health and welfare of current and future generations.” While no regulations are currently in place in the United States to regulate or phase out HFC refrigerants, the statement does establish the justification for future HFC regulations.

Figure 19-27 Comparison of both ozone-depletion potential and global-warming potential for several halogenated refrigerants.

CODE TIP

A European Union regulation in place since January 2011, known as the mobile air conditioner directive, or MAC, requires the refrigerant in new car air-conditioning systems to use refrigerant with a GWP of 150 or less. This requires auto manufacturers to find a replacement refrigerant for 134a. Many auto manufacturers are electing to use a new fluorinated refrigerant with an extremely low GWP of 4 called HFO 1234yf. It is a near drop-in replacement for 134a, so it requires very little system redesign. This new refrigerant is moving to the United States as well. General Motors has announced that they will be using HFO 1234yf in their new cars beginning with the 2013 models.

19.19 NAMING REFRIGERANTS

All modern refrigerants are named using a system of chemical nomenclature. The name describes a compound's chemicals and their arrangement. For example, monochlorodifluoromethane is the chemical name for R-22. This tells the reader that the chemical is composed of one chlorine (mono chloro) and two fluorines (di fluoro) attached to a methane molecule. However, these names are more useful to chemists than to air-conditioning technicians. Some simpler refrigerant naming conventions exist that help identify the makeup of some types of refrigerants in a more user-friendly manner.

Refrigerant Pseudonyms

Halogenated refrigerants are identified by a series of letters identifying the chemical element in the compound. The letters *C*, *F*, and *H* are used to represent chlorine, fluorine, and hydrogen. A final *C* is used to represent carbon.

These letters combine to identify the chemical components of the refrigerant.

- **CFC** contains chlorine, fluorine, and carbon.
- **HFC** contains hydrogen, fluorine, and carbon.
- **HCFC** contains hydrogen, chlorine, fluorine, and carbon.

Trade Names

Some manufacturers have created trade names to help promote their products. One of the most successful is Freon. Freon is DuPont's trade name for their line of CFC and HCFC refrigerants. Freon does not refer to a single refrigerant but a family of refrigerants. Another popular trade name is Puron. Puron is the Carrier corporation's trade name for R-410a. Puron does refer to a single refrigerant.

19.20 NUMBER DESIGNATION

Refrigerants are identified by number, preceded by the letter *R*, for "refrigerant." Some refrigerant numbering conventions exist that help identify the makeup of some types of refrigerants. These numbering designations were

originally developed by DuPont; have been established by the American Society of Heating, Refrigeration and Air Conditioning Engineers (ASHRAE); and are used throughout the industry.

Decoding Halogenated Refrigerant Numbering

The refrigerant number assigned to single-component halogenated refrigerants describes the number of each type of atom in the refrigerant molecule. Adding 90 to the refrigerant number yields a three-digit number, with each digit representing the number of a particular type of atom. The first digit on the left represents the number of carbon atoms, the second digit represents the number of hydrogen atoms, and the last digit on the right represents the number of fluorine atoms. Look at HCFC-22, for example: $22 + 90 = 112$.

The number shows that HCFC-22 contains one carbon, one hydrogen, and two fluorine atoms.

The number of chlorine atoms can be calculated using the information about the other components. The number of bonds available on a carbon-based molecule is twice the number of carbon atoms plus 2. For HCFC-22, which has one carbon atom, there are four bonds. Chlorine atoms occupy any remaining bonds after the fluorine and hydrogen atoms. Since HCFC-22 has four bonds and three of them are occupied, HCFC-22 contains one chlorine atom.

Let's look at another example: HFC-134a.

$$134 + 90 = 224$$

This indicates that R-134 contains two carbon atoms, two hydrogen atoms, and four fluorine atoms.

There are six bonds: $2 \times 2 + 2$. There are no bonds left over, so there are no chlorine atoms.

Isomers

Some halogenated refrigerants have a lowercase letter after their number, such as HFC-134a. The *a* at the end describes how these atoms are arranged. Isomers of a given compound contain the same atoms but are arranged differently. The atoms in compounds containing more than one carbon atom can usually be arranged in more than one way. Isomers usually have different properties from each other. Simply moving the components around changes the properties of the chemical. The letter following the number helps identify which isomer of the compound is being used.

The most symmetrical arrangement of atoms does not have a letter after the refrigerant number, as in HFC-134. The second most symmetrical arrangement is followed by the letter *a*, as in HFC-134a. If there is a third isomer, the third most symmetrical is followed by a *b*. Tetrafluoroethane has only two isomers: HFC-134 and HFC-134a, shown in Figure 19-28.

Zeotropic and Azeotropic Refrigerant Numbers

Zeotropic refrigerants all receive a 400 series number. The numbers following the 4 indicate the order that the refrigerant number was assigned by ASHRAE. The uppercase letter

Figure 19-28 Comparison of tetrafluoroethane isomers 134 and 134a.

after the number tells which percentage mix of the particular chemicals is used. For example, R-401A was the first blend assigned a number and the first percentage mix of the chemicals in R-401A. R-401B is composed of the same chemicals but with a different percentage of each chemical.

Azeotropic refrigerants all receive a 500 series number. Like zeotropes, the following two numbers identify the order in which the refrigerant was approved. Unlike zeotropes, azeotropes have no letter after the number because there is only one percentage mix where the components will behave like an azeotrope. For example, R-507 was the seventh azeotropic refrigerant to receive a number.

19.21 COMPATIBILITY

Refrigerants, like any chemical, can affect materials in detrimental ways. The effect of the refrigerant on the materials used in a system must be known. Preferably, the refrigerant should have no chemical or physical effect on the materials that the refrigeration system is built of. The refrigerant must not react with or deteriorate materials it comes in contact with during the operation. These include metallic compressor parts, gaskets, O-rings, seals, motor insulation and windings, piping, and condenser and evaporator heat-transfer surfaces.

Refrigerants will often cause swelling in plastics and elastomers. Petroleum-based refrigerants may dissolve some petroleum-based plastics. When designing plastic insulation, O-rings, and seals, this becomes important. However, this has seldom been any concern to the refrigeration technician. With the introduction of new HFC refrigerants,

the effect of a refrigerant on elastomers is suddenly of great concern. These new compounds are generally more chemically reactive than the older refrigerants they are designed to replace. This makes retrofitting an old system with new refrigerant difficult without technical information about the materials used inside the system. Systems should not be field retrofitted without the advice and consent of the equipment manufacturer.

Most refrigerants, including halogenated refrigerants, have no effect on any type of metal. There are some notable exceptions. Ammonia, still in wide use, chemically acts upon copper, brass, tin, and zinc. Therefore, all these metals are restricted from use with an ammonia system. Also, while pure ammonia is essentially inert to aluminum, ammonia and water mixtures will eat aluminum away. Aluminum is not a recommended metal for use with ammonia because of this.

Halogenated refrigerants are generally acceptable with most any common metal, but they should not be used with aluminum alloys containing more than 2 percent magnesium or zinc since both magnesium and zinc are reactive with a combination of halogenated refrigerants and water. HFC-410a is reactive with abraded aluminum. Abraded aluminum is aluminum that has been roughed up or ground up into pieces.

19.22 CONTAMINANTS IN REFRIGERANT

The only two chemicals that should be inside a refrigeration system are refrigerant and refrigeration oil. However, contaminants are often introduced through poor installation and service practices or through compressor failure. Contaminants that are frequently found in refrigerant include water vapor, acid, noncondensables, carbon, and particulates. When a refrigerant is recycled, many of these impurities can be removed. To resell the refrigerant, it must be reclaimed by a certified source and brought back to the original level of purity indicated by AHRI Standard 700-2006, which gives maximum allowable contamination levels for both new and reclaimed fluorocarbon refrigerants.

Water is undesirable in all but a very few refrigeration systems; notably, those that use water as either a refrigerant or an absorbent in an absorption-cycle machine. Water may cause numerous problems, such as the following:

- Freezing up at the metering device can cause a loss of system performance.
- Water can promote oxidation in the system.
- Water may hydrolyze the refrigerant and form powerful acids that will corrode the system.

Water is a great catalyst for chemical reaction; it accelerates many chemical reactions, such as oxidation. Since chemical reactions are very undesirable in a refrigeration system, water is most unwelcome. Most of the metallic parts inside a refrigeration system are not made to withstand corrosion since they are, in theory, exposed only to refrigerant and oil. Neither of these substances will corrode the metals used in the system, but water will corrode most any type of metal. Since nonresistant metals are used, a little water in the system can wreak havoc. While water will not cause any direct chemical reaction with halogenated refrigerants, water will

break down halogenated refrigerants in the presence of extreme heat. The temperatures on the discharge side of a compressor can be high enough to begin this process. Since halogenated refrigerants contain chlorine and fluorine, hydrochloric and hydrofluoric acids can form. These acids will eat away the metals in the system and attack the insulation of motor windings in hermetic compressors. Water can also be present in refrigerant cylinders. Using only clean, new refrigerant from a reliable source can effectively prevent this particular hazard.

TECH TIP

Noncondensables in a refrigerant cylinder or in a system will increase the pressure above the normal saturation pressure. A refrigerant cylinder with noncondensables will have a higher pressure than is indicated on a PT chart for its temperature.

19.23 REFRIGERATION OILS AND THEIR APPLICATIONS

Refrigerants need to be chemically compatible with the oil used in the system. Chemical reactions occurring between the system refrigerant and the oil are undesirable. Refrigeration oils and refrigerant must also be physically compatible. Most refrigeration systems depend on the refrigerant to carry the oil back to the compressor. In the best of all possible worlds, all the oil would remain in the compressor. However, in the real world it is impossible to keep all the oil in the compressor. Once the oil leaves the compressor, the only way to get it back is for the refrigerant to bring it back. For this to happen, the oil must be miscible with the refrigerant. Miscibility means that the oil will dissolve in the refrigerant in any proportion.

Mineral Oil

For years the primary oil in refrigeration systems has been mineral oil. Most CFCs and HCFCs are compatible with mineral oil. One of the primary challenges posed by HFC refrigerants is their incompatibility with mineral oil. Mineral oil is not the least bit miscible with HFC refrigerants. This means that once the oil has left the compressor, it does not return. Early work with HFC refrigerants and mineral oil showed that the oil tended to drop out at the first available opportunity, in the condenser. Normally, oil is more apt to drop out in the evaporator where the low temperatures thicken up the oil and make it more prone to separate. This tendency of oil to drop out in the condenser was dubbed "reverse solubility." This necessitated the development of new oils.

Polyalkylene Glycol

The first oil used with R-134a automotive systems was polyalkylene glycol, PAG. PAG is a cousin of the polyethylene glycol used as antifreeze in cars. Anyone who has

handled the glycol used for auto antifreeze knows that it is extremely slick and seems impossible to clean off. PAG oils are like a thick antifreeze. Glycol-based oils offer some challenges. They are chemically incompatible with CFCs, HCFCs, and mineral oil. Early attempts to convert R-12 systems to R-134a were frequently plagued by the formation of a sticky goo due to the incompatibility of PAG with both mineral oil and CFC refrigerant. PAG works well in new systems, but it proved too problematic for retrofit.

Like its antifreeze cousin, the glycol oils are very friendly with water. PAG sucks it up like a sponge, and this is not desirable for a refrigeration system. Materials like the glycols, which have an affinity for water, are called hygroscopic. PAG oil must be packaged in metal containers because it can literally suck water out of the air through plastic containers. PAG containers should not sit around on the shelf after they are opened, so PAG is best purchased in small quantities that are only opened immediately before use.

Polyol Ester

Polyol ester (POE) is the predominant oil of choice today. It is compatible with both old and new refrigerants and is also somewhat compatible with mineral oil. Ester oils are aggressive solvents, making material compatibility an issue. Ester-based oils can sometimes be used in retrofit situations, but they can be incompatible with the plastics and varnishes used in older systems. POE is also hygroscopic, and once mixed with water, it hydrolyzes to form acid. All systems containing POE must have a filter drier to avoid water contamination. Like PAG, it is shipped in metal containers. Also like PAG, it should be purchased in small quantities and only opened immediately before use.

Alkyl Benzene

Alkyl benzene is an older synthetic oil. It was designed to be used where mineral oil is used. Alkyl benzene can be used with zeotropic blends that contain a mixture of HCFCs and HFCs. Material compatibility is not as big an issue with alkylbenzene because it was developed for older systems.

Polyvinylether

A promising new refrigerant lubricant is polyvinylether, or PVE. It is compatible with all common refrigerants, including HFCs. It is not hygroscopic but instead is hydrophobic: it does not absorb or mix with water. It can be used in systems with small quantities of residual mineral oil or POE. Figure 19-29 shows refrigerant and oil compatibility.

19.24 REPLACEMENT REFRIGERANTS

All replacement refrigerants must be evaluated and approved by the EPA. The program that evaluates new refrigerants is called the Significant New Alternatives Policy, or SNAP. Substitutes are reviewed on the basis of ozone-depletion potential, global-warming potential, toxicity, flammability, and exposure potential. Lists of acceptable and unacceptable substitutes are updated several times each year.

TECH TIP

A “drop in” refrigerant can replace the original system refrigerant without any changes to the system, such as compressor oil changes, metering device adjustments, or seal changes. Although there are many advertised “drop in” replacement refrigerants, the EPA does not recognize any refrigerants as being true drop-in refrigerants requiring no system modifications or servicing.

The EPA lists alternative refrigerants as suitable for retrofit, new application, or unacceptable. Alternatives listed as retrofit refrigerants can be used to replace the refrigerant in an existing system. This does not mean that they will work with no system alterations, but they can be made to work in an existing system. Refrigerants listed as new alternatives will only work in new applications that accomplish the same thing. Sometimes these new alternatives are completely different approaches to cooling. One example is evaporative cooling, which is listed as an alternative for many types of systems. Evaporative cooling is a cooling system that reduces air temperature by evaporating water. Obviously, an evaporative system is a completely different type of system from a traditional mechanical refrigeration system. It is only a replacement in the sense that it accomplishes roughly the same thing as a mechanical refrigeration system if humidity control is not an issue.

There are some refrigerants that are specifically designed to replace CFCs or HCFCs in new equipment. HFC-134a replaces CFC-12 in new equipment but is not generally considered a retrofit refrigerant. HFC-407C is a very close replacement for HCFC-22 in retrofit situations. HFC-410A is the replacement for HCFC-22 in new equipment. It has pressures 40–60 percent higher than R-22, so it cannot be used as a retrofit. It is a replacement only in the sense that it is used in the same general types of cooling applications where HCFC-22 is used.

CODE TIP

There are many refrigerants available for retrofitting HCFC 22 systems, including R-407A, R-407C, R-417A, R-421A, R-422B, R-422C, R-424A, R-427A, and R-437A. However, using a new chemical in a refrigeration system will generally void the equipment’s third-party certification, such as UL or CSA, because the system was not tested by the testing organization with the new replacement refrigerant.

19.25 CHARACTERISTICS AND APPLICATIONS FOR REFRIGERANTS

The following information provides descriptions and tables for the properties of common refrigerants. The refrigerants are arranged by common application.

Refrigerants Primarily Used in Air Conditioning

R-22: monochlorodifluoromethane

Chemical family	HCFC Formulation Compound CHCl ₂ F
Safety rating	A1
Oil compatibility	Mineral oil, alkyl benzene, polyol ester
ODP	0.034
GWP	1,700

R-22 has been the refrigerant used in nearly all air-conditioning systems manufactured for several decades, from window units up to 25-ton commercial direct-expansion systems. It was used extensively in commercial refrigeration after the phaseout of CFCs, but low-temperature systems using R-22 often experience high compressor temperatures. It has a low ozone-depletion potential and a moderate global-warming potential. Because R-22 is an HCFC, it cannot be used in new equipment since January 1, 2010. It will no longer be manufactured or imported beginning January 1, 2020. The price of R-22 has risen dramatically in recent years as its production is being phased out.

R-407C: 23% pentafluoroethane, 25% difluoromethane, 52% tetrafluoroethane

Chemical family	HFC
Formulation	Zeotrope 23% R-125, 25% R-32, 52% R-134a
Safety rating	A1/A1
Oil compatibility	Polyol ester, poly alkylene glycol
ODP	0
GWP	1,700

HFC-407C is a high-glide zeotrope with a glide around 10°F. It is intended as a long-term replacement for HCFC-22. Its operating pressures are very close to those of HCFC-22. Its operating efficiency is less than HCFC-22. HFC-407C can be used as a retrofit refrigerant in many systems with a change in refrigeration oil. It must leave the cylinder as a liquid because it is zeotropic.

R-410A: 50% pentafluoroethane, 50% difluoromethane

Chemical family	HFC
Formulation	Zeotrope 50% R-125, 50% R-32
Safety rating	A1/A1
Oil compatibility	Polyol ester, poly alkylene glycol
ODP	0
GWP	2,000

HFC-410A is a low-glide zeotrope with a glide of 1°F or less. It has no ozone-depletion and a moderate global-warming potential. HFC-410A is the refrigerant that is replacing HCFC-22 in new air-conditioning applications. However, its pressure is 40–60 percent higher than HCFC-22, so it cannot be used to replace HCFC-22 in existing systems. The operating efficiency of HFC-410A tends to be higher than similar HCFC-22 systems. HFC-410A requires service tools designed for it because of its high pressures. Since it is zeotropic, HFC-410A must leave the cylinder as a liquid.

SAFETY TIP

In the air-conditioning/refrigeration industry there are no distinctions between the service valve connections for the different refrigerants used. This differs from the automotive industry, where different refrigerants have different-sized access ports to prevent the accidental use of an improper gauge set on an unapproved refrigerant. In air conditioning it is strictly up to the technician to make certain before attaching the gauge set to a system that it is the proper gauge set. This is significant when working around systems that may contain R-410a, because it has significantly higher pressure than most refrigerants used in the industry. Although the gauges will not explode, they can be overstressed to the point that they will no longer work properly.

Refrigerants Primarily Used in Commercial Refrigeration**R-404A: 44% pentafluoroethane, 52% trifluoroethane, 4% tetrafluoroethane**

Chemical family	HFC
Formulation	Zeotrope 44% R-125, 52% R-143a, 4% R-134a
Safety rating	A1/A1
Oil compatibility	Polyol ester, poly alkylene glycol
ODP	0
GWP	3,800

HFC-404A is a long-term replacement for the CFC-502 in new systems. HFC-404A is a low-glide zeotrope with a glide of 2°F or less. It has no ozone-depletion and a moderately high global-warming potential. It is primarily used in medium- and low-temperature systems, including commercial freezers, ice machines, and transportation refrigeration. HFC-404A is becoming the refrigerant of choice in low-temperature commercial refrigeration applications. Since it is zeotropic, it must be removed from the cylinder as a liquid.

R-507: 50% pentafluoroethane, 50% trifluoroethane

Chemical family	HFC
Formulation	Azeotrope 50% R-125, 50% R-143a
Safety rating	A1
Oil compatibility	Polyol ester, poly alkylene glycol
ODP	0
GWP	3,900

HFC-507 is a true azeotrope designed to replace CFC-502 in new commercial refrigeration applications. As an azeotrope, it may be removed from the cylinder as either a gas or a liquid.

Refrigerants Primarily Used in Domestic Refrigeration**R-12: dichlorodifluoromethane**

Chemical family	CFC
Formulation	Compound CCl_2F_2
Safety rating	A1
Oil compatibility	Mineral oil, alkyl benzene, polyol ester
ODP	0.82
GWP	10,600

CFC-12 was widely used for years in domestic refrigerators, automobiles, medium-temperature commercial refrigeration, and ice machines. It has both a high ozone-depletion potential and a high global-warming potential. It has been illegal to manufacture or import CFC-12 since January 1, 1996. Because of its previous widespread use, some systems are still in operation that use CFC-12.

R-134a: 1,1,1,2-tetrafluoroethane

Chemical family	HFC
Formulation	Compound CH_2FCF_3
Safety rating	A1
Oil compatibility	Polyol ester, poly alkylene glycol
ODP	0
GWP	1,300

This is a chlorine-free fluorinated refrigerant designed to replace R-12 in new appliances. It is generally not considered a retrofit refrigerant. It has an ODP of 0.0 and a GWP of 1,300. It is suitable for use in domestic refrigerators, automotive air conditioning, and medium- and high-temperature commercial applications. R 134a is also now widely used in high-pressure industrial chillers. It is a suitable replacement for R-12 wherever the evaporation temperature is -10°F or higher.

Refrigerants Primarily Used in Large Industrial Systems**R-11: trichlorofluoromethane**

Chemical family	CFC
Formulation	Compound CCl_3F
Safety rating	A1
Oil compatibility	Mineral oil, alkyl benzene, polyol ester
ODP	1
GWP	4600

CFC-11 was widely used in low-pressure centrifugal chillers. It has a high ozone-depletion potential and a moderately high global-warming potential. It has been illegal to manufacture or import CFC-11 since January 1, 1996. Because of its previous widespread use and the high cost of large centrifugal chillers, some systems are still in operation that use CFC-11.

R-123: 2,2-dichloro-1,1,1-trifluoroethane

Chemical family	HCFC
Formulation	Compound CHCl_2CF_3
Safety rating	B1
Oil compatibility	Mineral oil, alkyl benzene, polyol ester
ODP	0.012
GWP	120

This refrigerant was designed to replace R-11 in low-pressure chillers. The pressure-temperature curves show close performance characteristics between these two refrigerants. R-123 has a safety group classification of B1, making it objectionable from the standpoint of toxicity. As a result, some service companies refuse to use it. As yet, no new universally acceptable refrigerant has been developed to replace R-11. R-123 has a small ODP and a small GWP. Because R-123 is an HCFC, it will no longer be used in new equipment starting in January 2020. It will no longer be manufactured or imported beginning January 1, 2030.

R-717: ammonia

Chemical family	NH_3
Formulation	Compound
Safety rating	B2
Oil compatibility	Mineral oil
ODP	0
GWP	0

Ammonia is one of the oldest refrigerants in use today. It has a much higher latent heat of evaporation than the other common refrigerants. This means that smaller piping can be used. It is corrosive to copper but not to iron, steel, or aluminum. It therefore requires an all-iron, steel, or aluminum system, including the compressor, condenser, evaporator, controls, and piping. It is not destructive to the ozone layer. Its greatest defect is its toxicity and flammability. It has a safety rating of B2.

Due to ammonia's safety hazards, it is not found in appliances or normal comfort cooling applications. Typically it is used in large commercial or industrial applications where its operating efficiencies (lower horsepower per ton) are important and where plant engineers are available to operate the system. Examples would be dairies, ice cream plants, and large cold-storage facilities.

Due to its toxicity, an operator must take special precautions to limit the quantity inhaled. Leaks are detected by use of litmus paper, which changes color in the presence of ammonia, or a sulfur candle, which creates smoke in contact with ammonia. Technicians must also take care to avoid ammonia contact with the skin.

SERVICE TIP

In addition to the gloves and safety glasses that technicians should use with all refrigerants, there must be a self-contained breathing apparatus available for each worker in the area when working around systems that contain ammonia refrigerant. It is not possible to simply hold your breath and run from an area if an ammonia leak occurs. Part of the problem is the reaction the lungs have when a small quantity of ammonia is inhaled. Even a small amount of concentrated ammonia can damage lungs, and exposure to concentrated ammonia can temporarily blind you. The only way to prevent these problems is to have the appropriate equipment ready and available for emergency use.

UNIT 19—SUMMARY

Refrigerant is the fluid used in a refrigeration system to transfer heat. It does this by absorbing heat while evaporating at a low pressure and temperature and condensing at a high pressure and temperature. Refrigerants may be classified by many characteristics, including the following:

Operating Pressure

- Very high pressure
- High pressure
- Low pressure

Chemical Composition

- CFCs
- HCFCs
- HFCs

Formulation

- Compounds
- Zeotropes
- Azeotropes

Toxicity

- A: lower toxicity
- B: higher toxicity

Flammability

- 1: nonflammable
- 2: somewhat flammable
- 3: highly flammable

Ozone-Depletion Potential

- 0 ODP: no ozone depletion
- 1 ODP: high ozone depletion (CFC-11)

Global-Warming Potential

- 0 GWP: no global-warming potential
- 4,000 GWP or greater: high global-warming potential

The majority of modern halogenated refrigerants are built around the hydrocarbon molecules methane and ethane. Halogens replace some or all of the hydrogen atoms in the hydrocarbon molecules. CFCs and HCFCs have ozone-depletion potential because they contain chlorine. HFCs have no ozone-depletion potential because they contain no chlorine.

Refrigerant is available in disposable and refillable cylinders. Disposable cylinders should not be refilled by anyone with anything. Refillable cylinders are returned and refilled by the refrigerant manufacturer but should not be refilled by field technicians. Recovery cylinders are used in the field to recover refrigerant. They should not be refilled more than 80 percent full by volume because liquid expansion can cause hydrostatic pressures that can rupture the cylinders if they are filled completely with liquid.

UNIT 19—REVIEW QUESTIONS

1. Define *refrigerant*.
2. What organization has established the number designation for refrigerants?
3. What are the chemical components of CFC refrigerant?

Special Refrigeration Components

After completing this unit, you will be able to:

1. Identify each special refrigeration system component.
2. explain the purpose of each special refrigeration system component.

3. locate special refrigeration components on a refrigeration system.
4. discuss the need for filter driers in a refrigeration system.

There are a variety of refrigeration components that can be added to a basic refrigeration system to improve the operation of the system, increase system efficiency, enhance serviceability, provide system protection, or ensure safe operation. Service and installation technicians need to understand the operation and function of these

special components when working on a refrigeration system. Some are necessary for the proper operation of the system. In this unit we discuss the special refrigeration system components and their location in the refrigeration cycle, beginning at the compressor. Figure 20-1 shows the location of many common types of special refrigeration components in the refrigeration system.

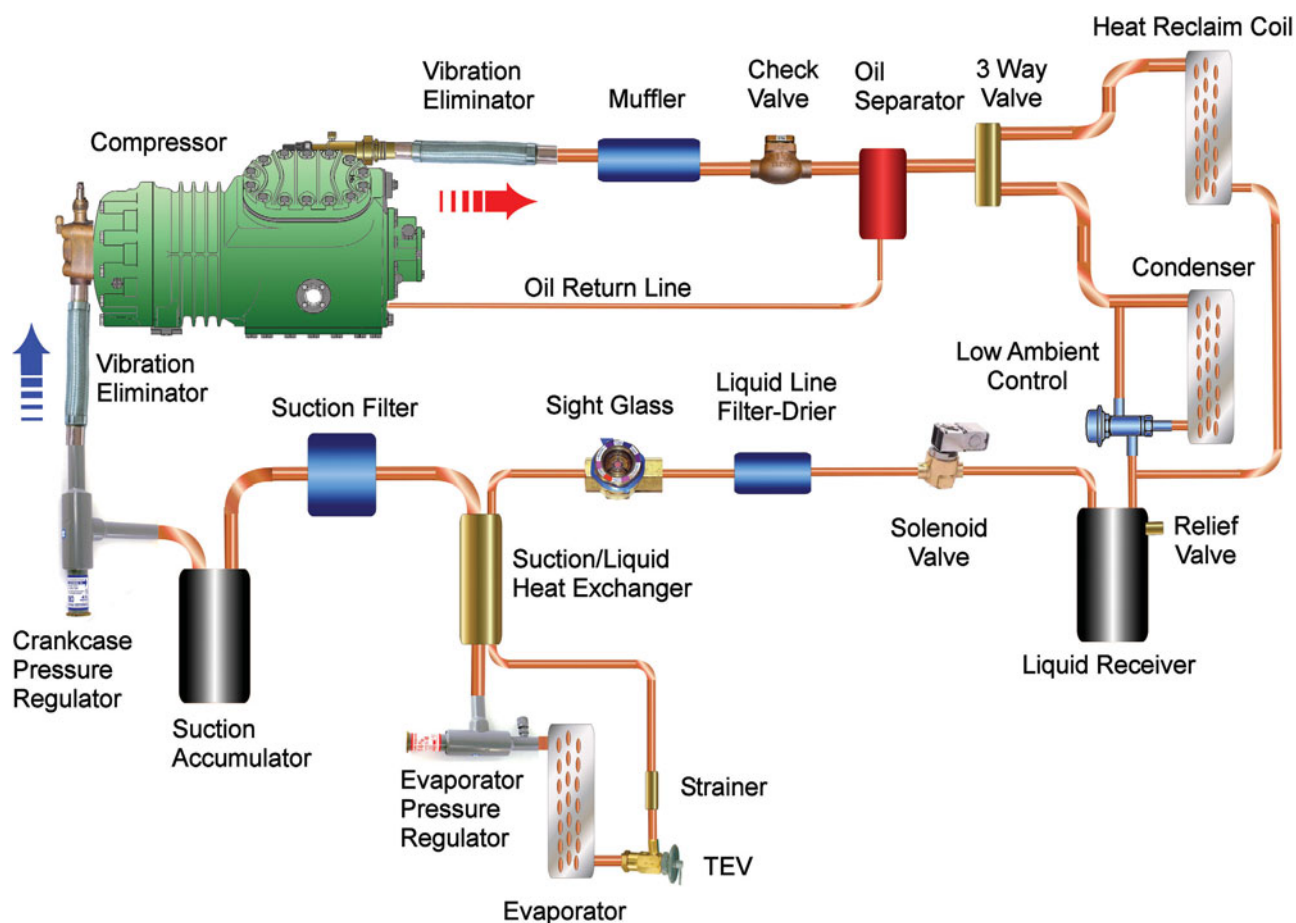

Figure 20-1 The location of common types of special refrigeration components in the refrigeration system.

SAFETY TIP

Refrigeration equipment contains various safety devices to protect equipment and people. Never bypass a safety device because a dangerous situation results that can lead to personal injury or equipment damage. Notify the system owner if a safety device is bypassed, and make the safety device operational.

20.2 VIBRATION ELIMINATORS

As a compressor operates, it produces some vibrations in the suction line and discharge line. On larger systems the vibration could cause abnormal stress on the lines, which could lead to refrigerant leaks on those lines. Vibration eliminators are used to absorb some of the vibration created by the compressor. They can be located at either the inlet or the outlet of the compressors (see Figure 20-1). Typically they are made of flexible bronze tubing that expands and contracts like an accordion. Braided bronze strips with copper absorb the vibrations and prevent overstressing the copper lines leading to and from the compressor. Figure 20-2 shows a vibration eliminator.

20.3 HOT GAS LINE MUFFLERS

Mufflers are used on systems to reduce the noise that can be produced by the gas pulsations of the refrigerant being compressed and pumped by a compressor. Mufflers are normally installed on the discharge line of the compressor (see Figure 20-1). A typical discharge-line muffler is shown in Figure 20-3. They are made of a brazed or welded cylinder with baffle plates mounted on the inside. Compressor manufacturers can also install a muffler inside the compressor. Most hermetic reciprocating compressors have discharge mufflers inside their shell. When a muffler is added to a system, it will commonly be placed in the discharge line as close to the compressor as possible.

Figure 20-2 Suction-line vibration eliminator

Figure 20-3 Hot gas line muffler.

20.4 CHECK VALVES

Check valves are used on some larger refrigeration systems to ensure that the refrigerant flows in one direction only. They are located on the discharge line, usually near the compressor (see Figure 20-1). Figure 20-4 shows a refrigeration check valve used to prevent liquid refrigerant from flowing back to the compressor from the condenser during the off cycle of the system. Liquid refrigerants returning to the compressor during the off cycle can seriously harm the compressor on startup. These valves are also used on systems with two evaporators operating at different temperatures and controlled by a single condensing unit. A check valve is placed in the suction line of the lower-temperature evaporator to prevent the suction vapor from the higher-temperature evaporator from entering the lower-temperature evaporator.

20.5 OIL SEPARATORS

Reciprocating and rotary compressors will discharge some oil with the refrigerant as it leaves the compressor. This oil will then travel with the refrigerant throughout the system

Figure 20-4 Refrigerant check valve.

Figure 20-5 Oil separators used to remove oil from the discharge gas. (Courtesy Danfoss Inc.)

and eventually return to the compressor's crankcase. For the oil to travel with the refrigerant throughout the system, good piping practices must be employed. Poor piping practices can lead to oil being trapped out in the system, preventing it from returning to the compressor. If enough oil is trapped out in the system, the compressor could become starved for oil and bearing damage could occur.

Oil separators are used to separate and collect some of the oil in the discharge line as it leaves the compressor and return it to the compressor's crankcase. They are located in the discharge line (see Figure 20-1). Figure 20-5 shows an oil separator. The refrigerant/oil mixture discharged from the compressor enters the oil separator; the velocity of this mixture is slowed down from the use of internal baffles and impingement screens. This slowing down of the refrigerant/oil mixture causes a major portion of the oil to drop out of the mixture and fall to the bottom of the oil separator.

At the bottom of the oil separator is a float assembly connected directly back to the crankcase of the compressor. As the oil level at the bottom of the oil separator increases, the float will cause a valve to open, and, due to the pressure difference between the oil separator and the compressor's crankcase, some of the oil will be returned to the compressor's crankcase.

Although oil separators can be quite efficient (some will be as high as 98 percent efficient), they do not separate all of the oil from the refrigerant. Some quantity of oil will always travel with the refrigerant throughout the system. Good piping practices must always be followed while in-

Figure 20-6 Typical three-way valve on a system.

stalling a system. Even with an oil separator, poor piping practices will eventually lead to oil being trapped out in the system, causing a deficiency of oil in the compressor's crankcase.

Oil separators are often used on supermarket rack systems with multiple compressors connected together to a common manifold. Oil management is necessary when operating several compressors on the same system to ensure that each compressor receives proper lubrication.

20.6 THREE-WAY VALVES

Some larger refrigeration systems will reclaim the heat from the discharge vapor leaving a compressor and use this heat to either assist the heating of the building or assist in the heating of the domestic hot water for the building. The three-way valve directs the flow of the refrigerant to either the condenser or the heat-reclaim coil. Three-way valves used for heat reclaim are located in the discharge line between the compressor and the condenser (see Figure 20-1). Figure 20-6 shows a typical three-way valve on a system.

20.7 HEAT-RECLAIM COILS

When it is possible to reclaim some of the heat from the hot discharge gas, the three-way valve sends it to another heat exchanger, commonly referred to as a heat-reclaim coil, shown in Figure 20-7. This heat exchanger will extract some useful heat from this discharge vapor and then the cooler discharge vapor will be piped to the system's condenser. Heat-reclaim coils used for heating air are located in the air-handling equipment. They are used to provide heat in the winter in supermarkets or for reheating the discharge air during dehumidification.

GREEN TIP

Heat-reclaim coils improve a building's overall efficiency by using waste heat that would normally be thrown away to heat the building or hot water.

20.8 LOW AMBIENT CONTROLS

Many large refrigeration systems are designed with outdoor air-cooled condensers. Air-cooled condensers can provide free subcooling and lower condensing pressures during low ambient conditions. However, there is a downside to low ambient operation: if the condensing pressure falls too low, it will cause the metering devices at the refrigerated cases to underfeed. Typically, thermostatic expansion valves (TEV) are used as the metering device on these systems. A standard TEV requires a minimum pressure difference across its port to properly feed refrigerant into the evaporator. If the pressure difference across the TEV drops below a minimum value, the valve will not feed enough refrigerant into the evaporator, starving it. Low ambient controls are designed to maintain a minimum liquid pressure during low ambient conditions.

One method of elevating the system liquid pressure is to control the operation of the condenser fan motors. A system can be designed to either cycle the condenser fan motor(s) on and off as needed, or the speed of the condenser fan motor(s) can be controlled to maintain a minimum condensing pressure. As the condensing pressure falls, the condenser fan motor(s) are either cycled off or slowed down to reduce the amount of air flowing across its coils. This reduces the condenser's ability to reject the heat from the refrigerant, and its pressure increases. Fan cycling is often used for small systems with refrigerant-cooled compressors because of its simplicity.

TECH TIP

Fan cycling should never be used on air-cooled compressors. Air-cooled compressors depend on the airflow from the condenser passing over the compressor body to cool the compressor. Shutting off the condenser fan during cold weather can actually cause the compressor to overheat.

Many commercial refrigeration systems maintain a minimum liquid pressure using condenser flooding controls. They work by controlling the flow of refrigerant through the condenser using an OROA pressure regulating valve (Figure 20-8). OROA valves "open on rise of outlet" pressure. They are preset, so they must be carefully selected to match the refrigerant and the system in which they will be used. This control is installed at the outlet of the condenser, with a line going back to the condenser inlet, as shown in Figure 20-1. When the liquid pressure falls below a preset minimum, the regulator will close down, causing the refrigerant to back up in the condenser, flooding it with liquid refrigerant. This reduces the condensing surface, causing the condensing temperature and pressure to increase. While the flow leaving the condenser is restricted, the OROA valve will bypass a portion of the discharge vapor directly to the receiver to maintain a minimum liquid pressure in the receiver. When the receiver pressure increases above the valve setting, the

Figure 20-8 Open on rise of outlet pressure head pressure-control valve.

OROA valve will open, allowing the high-pressure liquid to leave the condenser and enter the liquid receiver.

GREEN TIP

Low ambient controls force the compressor to work harder than it normally would need to in cold ambient temperatures. Improved refrigerant metering devices are available that allow the system to operate at much lower pressure drops across the metering device, reducing or eliminating the need for low ambient controls. Since compressors use less energy when operating at lower discharge pressures, using advanced refrigerant metering devices to reduce the need for low ambient control improves system efficiency.

20.9 RECEIVERS

A receiver is a vessel that allows a system to store excess refrigerant that it does not currently need. A typical receiver is shown in Figure 20-9. Liquid receivers are normally used on systems with modulating metering devices, such as TEVs. When the TEV throttles, the receiver provides a place for the excess refrigerant to go. When the TEV opens, the stored refrigerant can be used. Only systems that have the ability to regulate the flow of refrigerant and are exposed to varying heat loads should have a receiver installed. Liquid receivers are not used with fixed restrictions such as orifices or capillary tubes.

Receivers are normally installed in the liquid line of a system after the condenser and before the metering device (see Figure 20-1). The inlet connection of the receiver will allow refrigerant to enter the top of the receiver. The outlet of the receiver will be connected to an internal dip tube connected to the bottom of the receiver. This ensures that only liquid refrigerant leaves the receiver and travels to the system's metering device.

Receivers are typically designed to hold 20 percent more than the entire system's refrigerant charge. This additional

Figure 20-9 Liquid receiver showing inlet and outlet valves and safety relief.

20 percent allows a vapor cushion to exist within the receiver so that it cannot become overfilled with refrigerant.

The service valve installed at the outlet of the receiver is referred to as the king valve. This valve is very useful for a service technician. It allows a technician to read the system's pressure at the receiver as well as trap the system's refrigerant charge in the condenser and receiver. This allows a technician to work on any section of the system from the outlet of the king valve to the inlet of the compressor without having to recover the refrigerant charge.

20.10 RELIEF VALVES

Relief valves are used to release abnormally high pressure inside a vessel before the pressure causes it to erupt. They are normally located on a system's condenser or receiver, but they can be located on any other vessel on a system. There are two basic types of relief valves: automatic relief valves and one-time relief valves.

Automatic relief valves are spring-loaded valves normally encased in a brass body with a neoprene seat. They are designed to automatically reset once the pressure inside the vessel reaches a safe level. They will be located on a section of the vessel where refrigerant vapor is located. This allows only the vapor to be released from the vessel rather than any liquid refrigerant. Some automatic relief valves will also have a thread connection on the top to allow piping to be attached to it so the released refrigerant can be vented out of the building or mechanical room where the vessel is located.

A one-time relief valve, sometimes called a fusible plug, is a valve that cannot be reset once it releases the pressure from a vessel. It is normally constructed from a fitting with a drilled hole filled in with a low-temperature solder. At a specific temperature the solder will soften and pressure within the vessel will cause the solder plug to blow out and release

the refrigerant within the vessel. Once the solder plug blows out of the fitting, the relief valve must be replaced.

20.11 SOLENOID VALVES

A solenoid valve is a flow-control device that stops or allows the flow of a refrigerant in a refrigeration system. It can be installed in any of the refrigerant lines. Most commonly, it is installed in the liquid line to stop or allow the flow of liquid refrigerant into the metering device and the evaporator (see Figure 20-1).

Solenoid valves are available as normally open or normally closed. When voltage is applied to the coil of a normally closed valve, it picks up the plunger and allows the flow of refrigerant through it. When voltage is no longer applied to the coil, the plunger will close due to an internal spring and system pressures. When voltage is applied to the coil of a normally open valve, it will close and stop the flow of refrigerant through it. When voltage is no longer applied to the coil, the valve will again open and allow refrigerant to flow through it.

The direction in which a solenoid valve is installed is important to its proper operation. Normally there will be an arrow stamped on the body of the valve to indicate the direction of refrigerant flow (Figure 20-10). If installed incorrectly, the solenoid will not properly shut down and stop the flow of refrigerant when needed.

A typical solenoid valve consists of two parts: the valve body and its electrical coil. Figure 20-11 shows a picture

Figure 20-10 The solenoid must be installed with the arrow pointing in the direction of refrigerant flow.

of a solenoid valve. When purchasing a solenoid valve, both parts are normally ordered separately, allowing a technician to use the same valve body with different coil voltages.

20.12 LIQUID-LINE FILTER DRIERS

The filter drier's job is to keep the system clean and dry. Filter driers are designed to remove three types of contaminants: particles, moisture, and acid. Filter driers normally incorporate a screen to filter out any debris in the system that could potentially clog the small orifice in the metering device. Particle debris found in refrigeration systems includes dirt, oxide, carbon, flux, and metallic particles. Other contaminants would include sludge and wax formed by oil breakdown. This debris can damage cylinder walls and bearings and plug metering devices and screens.

Filter driers also have desiccant inside that absorbs water vapor and acid in the refrigerant. Water vapor is very harmful to a refrigeration system, and even a very small amount of moisture can cause serious system problems. Excessive amounts of water vapor can cause two problems: (1) it can freeze at the metering device, causing a restriction, or (2) it can react with heat and oil inside the compressor to produce sludge, wax, and acids. Acid formation starts in systems with POE (polyol ester) lubricant with water concentrations as low as 75 ppm (parts per million).

Filter driers must also be able to remove acids from the system. Chemical interactions between the refrigerant, the lubricants, and moisture can form acid in the system. This is particularly true for systems that use POE lubricant. POE is made by combining alcohol and acid to form polyol ester and water. Adding water and heat can reverse the process, forming alcohol and acid inside the system. This is known as hydrolysis.

Desiccants are the materials used to remove water from the refrigerant. The two desiccants most often used in filter driers are molecular sieve and activated alumina. Molecular sieve is superior at moisture removal but is less effective on acids. Activated alumina is effective on both organic and inorganic acids but is less effective at moisture removal. Activated charcoal is often added to help remove hydrocarbon residues and wax. The mix of desiccant materials in the drier depends upon its intended use. A drier that is used on new equipment to help with dehydration will have more molecular sieve, while a drier that is used for cleaning a system after a compressor burnout may have more activated alumina.

Two methods are used to hold the desiccant materials in the driers. One method mixes different types of desiccant material and forms it into a solid molded core (Figure 20-12). The other uses individual desiccant beads that are compressed together inside the shell (Figure 20-13). Standard filter driers have a definite inlet and outlet with arrows indicating the direction of refrigerant flow (Figure 20-14). Piping the drier in backwards can decrease its ability to filter out particles. Driers intended for use with heat-pump systems are designed to allow flow in either direction. These are called bi-flow driers. Their ability to allow flow in either direction is normally indicated with arrows pointing in both directions (Figure 20-15).

Figure 20-14 This filter must be installed with the refrigerant flowing in the direction of the arrow.

Figure 20-15 The arrows pointing in either direction indicate that this is a bi-flow drier.

SERVICE TIP

One advantage of driers with flare connections is that they are easier to replace.

Small driers for residential systems are one piece inside a welded steel shell (Figure 20-16). The entire drier shell and its desiccant must be removed and discarded when the drier is changed. These driers are available with either brazed or flared connections (Figure 20-17). Replaceable core driers

are available for larger systems. For these, the shell remains in place and the drier cores are replaced (Figure 20-18).

SAFETY TIP

Always make sure that the filter drier you are installing is rated for the refrigerant the system uses. For example, HCFC 410A systems operate at substantially higher pressures than HCFC 22 systems. Using a drier intended only for HCFC 22 on an HFC 410a system could result in the drier shell rupturing.

A filter drier should be installed with all new refrigeration systems that use POE lubricants, because POE is such a hygroscopic material. Even a deep evacuation will not remove moisture from POE. The filter drier should be replaced anytime a refrigeration system is opened for service, regardless of refrigerant type. The pressure drop across a filter will increase when the filter is clogged. Normally, a filter drier with a pressure drop exceeding 2 psig should be replaced. Driers should not be removed by debrazing. Heating the drier with a torch will cause the desiccant to release some of the contaminants back into the system. Instead, brazed-in driers should be cut out to ensure that the contaminants remain in the drier.

SAFETY TIP

Always make sure the refrigerant has been recovered or the system pumped down before removing a liquid-line filter drier.

**Figure 20-19** Liquid-line sight glass moisture indicator.

20.13 SIGHT GLASSES/MOISTURE INDICATORS

A sight glass can be added to the liquid line to allow a technician to view the condition of the refrigerant in the liquid line at the point it is located. A typical liquid-line sight glass is shown in Figure 20-19. On a properly operating system, the liquid line should contain only liquid refrigerant. A sight glass will show this condition, as only clear liquid will be seen flowing through the sight glass. If vapor exists along with the liquid refrigerant, it will be seen flowing through the sight glass along with the liquid refrigerant.

An indicator can also be added to a sight glass to help indicate the moisture content of the refrigerant. The indicator is a porous filter paper impregnated with chemical salt that is sensitive to moisture. A technician can view the indicator in the sight glass and the color of the paper will show the moisture content of the refrigerant. A common color-coding system is green for a dry system and yellow for a wet system. Always check with the sight glass manufacturer to verify their color-coding system.

20.14 STRAINERS

Strainers are similar to filter driers except there is no desiccant inside to absorb the moisture in the system. Strainers are simply filters used to prevent solid particles from entering metering devices and causing a restriction. They are normally located just ahead of the metering device (see Figure 20-1). Capillary tube systems often have strainers between the liquid line and the capillary tube (Figure 20-20).

20.15 EVAPORATOR PRESSURE REGULATORS (EPR)

An evaporator pressure regulator (EPR), such as that shown in Figure 20-21, is a refrigerant flow-control device that prevents the refrigerant pressure in the evaporator from operating below a minimum value. It is normally installed in the suction line just after the outlet of the evaporator (see Figure 20-1). EPR valves are normally used on systems with multiple evaporators operating at different

Figure 20-20 Capillary-tube systems often have strainers just before the capillary tubes.

Figure 20-21 Evaporator pressure regulating (EPR) valve.

evaporating pressures. Each of the evaporators operating at a pressure higher than the lowest on the system will have an EPR installed at its outlet. The EPR will prevent these evaporators from operating at the lower operating pressure. An EPR can also be used as a safety, such as on a water chiller, to prevent the evaporator pressure (temperature) from dropping too low and freezing the water in the chiller barrel.

An EPR is an "open on rise of inlet" pressure regulator. The two forces that regulate the port opening on this type

of valve are an internal spring pressure and the regulator inlet evaporator pressure. The outlet pressure of the regulator has no factor in the opening or closing of this regulator. The internal spring pressure is the closing force, and the inlet evaporating pressure is the opening force. As the inlet pressure drops, the internal spring pressure will start to close down the port, preventing the inlet (evaporator pressure) from dropping below its setting. As the inlet pressure increases, the port will open until it reaches its maximum port size. Once its maximum port size has been reached, the evaporator pressure can continue to rise. The EPR does not control or regulate the maximum operating evaporator pressure of a system; it only prevents this pressure from dropping below a minimum setting. Some evaporator pressure regulators are designed to pop open and close rather than continuously modulating.

The selection of an EPR is based on the system conditions, such as the refrigerant used in the system, the evaporator design capacity, and the available pressure drop across the valve at its design load. Check the manufacturer's selection table to determine what conditions are required for the proper valve selection. These valves should not be selected based simply upon on the suction line size, since a manufacturer may use the same line size for many different capacities.

Adjusting an Evaporator Pressure Regulator

To adjust the control point of an EPR, first attach a pressure gauge on the inlet side of the regulator. Turn its adjustment screw clockwise to increase the valve's control point and counterclockwise to decrease its control point. It may take up to thirty minutes for the new balance to take place after an adjustment is made. If the valve is being adjusted to a lower setting, an immediate response to an adjustment should be noticed. Adjustments to an EPR should be made when the evaporator is under a minimum load condition.

20.16 SUCTION-LINE FILTERS

Suction-line filters are installed in the suction line before the compressor (see Figure 20-1) and are used to protect the compressor from contaminants in the refrigeration system. Suction-line filters are often added after a compressor burnout to protect the replacement compressor. Suction filters contain the same desiccants that are found in liquid-line filter driers, but often in mixtures that enhance the removal of acids and particulates. Suction filters must have a large cross-sectional area because gas travels through them, not liquid. The larger area helps reduce pressure drop through the filter since filter pressure drop adversely affects the system efficiency. Suction filters are usually removed after the system has been cleaned, or if the filter becomes so loaded with contaminants that there is a significant pressure drop across the filter. Most suction-line filters have Schrader ports that allow technicians to check the pressure drop

Figure 20-22 Suction-line filter drier.

across the filter (Figure 20-22). In large systems, replaceable core shells can be used in the suction line.

20.16 SUCTION-LINE ACCUMULATOR

The suction accumulator is located in the suction line just before the compressor (see Figure 20-1). The suction-line accumulator stores refrigerant and helps prevent liquid refrigerant from returning to the compressor. Small quantities of liquid refrigerant returning to a compressor can cause bearing washout. The liquid refrigerant returning to the compressor mixes with the oil and is then used to lubricate the bearings within the compressor. This mixture is a very poor lubricant and will lead to premature bearing failure. Large quantities can cause liquid slugging if liquid gets in the compressor cylinders. When the compressor tries to compress the liquid, pressures increase to thousands of psi and parts break.

While suction accumulators can be applied to most types of systems, they are often used on systems that cannot use liquid receivers but have a need to store refrigerant. Heat pumps are a very common example. They cannot use a liquid receiver because the coil serving as the condenser changes depending upon the cycle. The amount of refrigerant circulating through the system ranges from less than half the charge during cold-weather heating to all the charge in hot-weather cooling. The accumulator gives the extra charge a place to sit without adversely affecting system operation.

The basic design of a suction-line accumulator is a U-shaped tube enclosed in a large-volume vessel. A cutaway view of a suction-line accumulator is shown in Figure 20-23. One end of the U-shaped tube is connected to the suction line leading back to the compressor, and the opposite end is open to the tank. The suction line from the evaporator is then connected to the top of the shell of the tank. If any liquid refrigerant enters the accumulator, it will

Figure 20-23 Cutaway view of a suction-line accumulator.

be exposed to a large volume of the tank, causing it to evaporate and return only refrigerant vapor to the compressor. There are also two small holes drilled into this U-shaped tube. One small hole is drilled at the bottom bend of the U-shaped tube. This allows a small amount of oil and liquid refrigerant, which collects on the bottom of the tank, to be safely metered back to the compressor. Another small hole is drilled at the top end of the U-shaped tube and is referred to as a pressure-equalization orifice. When the system shuts down, it is possible for liquid refrigerant to collect in the bottom of the suction-line accumulator, and because of the small hole drilled in the bottom bend of the U-shaped tube, liquid refrigerant will also collect in this tube. On startup, liquid refrigerant could then be sucked out of the U-shaped tube and return to the compressor. To prevent this from occurring, a small hole is drilled at the top end of the U-shaped tube. The small hole equalizes the pressure on both sides of the liquid in the U-shaped tube and prevents the liquid refrigerant from being sucked out of the tube on startup.

Some suction-line accumulators will have a section of the liquid line run through its bottom section. This warm liquid refrigerant helps to evaporate any liquid refrigerant that collects at the bottom of the accumulator. Another benefit to this design is that the liquid refrigerant in the liquid line will gain additional subcooling, increasing the net refrigeration effect of the system.

SERVICE TIP

A suction-line accumulator should not be used to solve a system problem that is causing liquid refrigerant to return to a compressor. If liquid refrigerant is returning to a compressor, the root cause should be identified and repaired.

SERVICE TIP

Accumulators will collect contaminants and debris. Particles become trapped in the accumulator after any major system contamination, such as a compressor burnout. Accumulators have a J-shaped tube that pulls in gas at the top, dips down into the oil at the bottom, and sucks in a small quantity of oil as the gas leaves the accumulator. The small hole in the J tube can become clogged, interfering with oil return to the compressor. This can lead to a second compressor failure. Accumulators should be removed and flushed or replaced after a major compressor burnout.

20.17 CRANKCASE PRESSURE REGULATORS (CPR)

Crankcase pressure regulators (CPR) are commonly added to many low-temperature refrigeration applications, such as walk-in and reach-in freezers. A typical CPR is shown in Figure 20-24. They prevent the compressor's motor from overloading when the crankcase pressure rises above its designed level. On many low-temperature applications, this can occur during or after a defrost cycle or upon restarting after a normal shutdown period. Compressor overload is likely when starting, especially if the cooler/freezer is at ambient temperature. The CPR is an outlet pressure regulator and will not allow the crankcase pressure to rise above a predetermined level.

The CPR is installed in the suction line just before the compressor (see Figure 20-1). Normally there are no other components installed downstream between the outlet of the CPR and the compressor. This is to ensure that the outlet of the CPR senses the true crankcase pressure of the compressor.

It is not recommended that this type of regulator be used on a system that also uses a maximum operating

pressure (MOP)-type of expansion valve. The use of both of these valves on the same system may cause longer pull-down times. This, however, may be overcome if the pressure settings of both valves are sufficiently spread apart. When using a CPR on a system that is also using a discharge bypass valve for capacity control, the pressure setting of the CPR must be higher than that of the bypass valve.

The typical CPR is a close-on-rise regulator. The outlet pressure (crankcase pressure) of the valve is the closing force within it. The opposing opening force within the valve is an interior spring. These two forces oppose each other to regulate the port size within the valve. The interior spring is adjustable to apply a maximum opening force. If the pressure applied at the outlet of the valve (crankcase pressure) is above the spring force, the valve will close down. The inlet pressure of the CPR has no effect of the operation of the valve. The inlet pressure is applied equally to both the underside of its bellows and the top of its valve seat disc, canceling out the effect of the inlet pressure.

The selection of a CPR is based on five basic system conditions:

1. Refrigerant
2. Refrigeration capacity of the system
3. Design suction pressure of the system
4. Maximum crankcase pressure recommended by the compressor manufacturer
5. Pressure drop across the valve at design load conditions

Once these conditions are known, a valve can be chosen from the manufacturer's selection table. These valves should not be selected based on the line size of suction line, since a manufacturer may use the same line size for many different capacities.

Servicing Crankcase Pressure Regulators

The control setpoint of a CPR will need to be adjusted on the startup of a new system or anytime the valve is replaced. Always refer to the instructions provided by the manufacturer when adjusting these valves. If the instructions are not available, the following guidelines can be helpful:

- Allow the system to be off long enough to allow the pressures to stabilize and the evaporator pressure to reach a high level—one that would simulate the pressure during or after a defrost period or during the initial startup of the case.
- Turn the adjustment screw on the valve all the way out (normally this is done by turning the screw counterclockwise) so that the valve is set to an initial low setting.
- Start the system and observe both the crankcase pressure and the amperage draw of the compressor. Slowly turn the adjustment screw in (normally this is done by turning the screw clockwise) until the amperage draw reaches the maximum allowed by the compressor manufacturer.

This should allow a technician to achieve an acceptable setpoint for the valve. Some systems may have two CPRs that are piped in parallel. When adjusting these valves, both will need to be adjusted at the same time and at the same

Figure 20-24 Crankcase pressure regulator (CPR).

Figure 20-25 A suction-to-liquid heat exchanger transfers heat from the warm liquid passing through the small, coiled tubing to the cool suction gas passing through the shell.

rate. This will ensure that the load is divided equally across both valves.

20.18 SUCTION-TO-LIQUID HEAT EXCHANGER

A suction-to-liquid line heat exchanger can be added to improve system efficiency and help prevent liquid from returning to the compressor. Normally, the low-pressure suction line and the high-pressure liquid line are piped next to each other as they travel between the condensing unit outside and the evaporator inside. The suction-to-liquid heat exchanger is installed in both the suction line and the liquid line (see Figure 20-1). The heat exchanger is a shell with a coil of tubing inside (Figure 20-25). The suction gas passes through the shell of the heat exchanger and the liquid passes through the tubing coiled inside the shell. Heat is transferred between the cool vapor in the suction line returning to the compressor and the warm liquid refrigerant passing through the tubing on its way to the metering device. This warms the cool suction gas and cools the warm liquid. The effect is to increase both suction gas superheat and liquid subcooling. The increased subcooling adds system efficiency by preventing flash gas in the liquid line and reducing the amount of flash gas formed in the metering device.

Figure 20-26 Refrigeration service valve.

20.19 ISOLATION VALVES

Isolation valves are used to isolate system components when servicing a system. Isolation valves can be stem-type refrigeration service valves (Figure 20-26), diaphragm valves (Figure 20-27), or ball valves (Figure 20-28). Ball valves are often preferred over other valves because they cause less restriction to the flow of refrigerant. It is advantageous to service technicians to be able to isolate a component when servicing systems. Once a component is isolated from the rest of the system, only the refrigerant charge for that component needs to be removed to service that component, not the entire system charge. When working on systems with a large refrigerant charge, having isolation valves installed can save much time for a technician.

SAFETY TIP

Only valves specifically designed for refrigeration equipment should be used for isolation valves in a refrigeration system! Valves designed for lower pressures, such as water valves, can rupture when exposed to refrigeration pressures. Valves should also be rated to withstand pressures normally generated by the refrigerant in the system. Valves rated for HCFC 22 may not be safe if installed in an HFC 410A system.

UNIT 20—SUMMARY

There are many components that could be added to the basic refrigeration system. Some of these components are designed to improve the operation of a system, while others are safety components that protect the major system components and equipment owner. Special refrigeration components discussed in this unit include the following:

- Vibration eliminators prevent compressor vibration from being transmitted to the lines.
- Mufflers reduce the noise produced by the gas pulsations of the refrigerant being compressed and pumped by the compressor.
- Check valves ensure that the refrigerant flows in one direction only.
- Oil separators remove oil in the discharge gas and return it to the compressor's crankcase.
- Three-way valves direct hot gas to either the condenser or a heat-reclaim coil.
- Heat-reclaim coils take waste heat in the discharge gas and use it to heat air or water.
- Low ambient controls maintain a minimum liquid pressure during low ambient conditions.
- A receiver allows TEV systems to operate properly by storing excess refrigerant.
- Relief valves release excess pressure inside the receiver before the pressure causes it to burst.
- Solenoid valves control the flow of a refrigerant by using an electromagnetic coil to open or close the valve.
- A liquid-line filter drier has a screen inside that filters out debris and desiccant that absorbs water vapor in the system.
- A sight glass allows a technician to view the condition of the refrigerant in the liquid line at the point it is located.
- An evaporator pressure regulator (EPR) prevents the evaporator pressure from dropping below the setpoint of the EPR valve.
- Strainers filter solid particles out of the refrigerant entering the metering devices.
- Suction filters protect replacement compressors by removing contaminants from the suction gas.
- Suction-line accumulators prevent liquid refrigerant from returning to the compressor.
- A crankcase pressure regulator (CPR) prevents compressor overload by keeping the crankcase pressure below the CPR setpoint.
- A suction-to-liquid line heat exchanger improves efficiency, increases the system superheat, and increases system subcooling.
- Isolation valves include refrigeration service valves, diaphragm valves, and ball valves. They are used to isolate system components.

UNIT 21

Plotting the Refrigeration Cycle

OBJECTIVES

After completing this unit, you will be able to:

1. explain how refrigerant heat, pressure, and temperature change as refrigerant flows through a refrigeration system.
2. identify the lines and scales on a PH (pressure-enthalpy) diagram.
3. draw a PH diagram of a basic refrigeration cycle.

21.1 INTRODUCTION

Pressure-enthalpy (PH) diagrams are primarily used for designing refrigeration systems. All aspects of system performance can be predicted using a PH diagram. A system's refrigeration capacity, the amount of refrigerant that must be circulated, the amount of heat absorbed by the evaporator, the amount of heat rejected by the condenser, and the required compressor capacity can all be determined using a PH diagram. Technicians can use PH diagrams to troubleshoot systems by comparing a plot of what a system is doing to what it should be doing.

21.2 PRESSURE-ENTHALPY DIAGRAMS

Pressure-enthalpy diagrams are referred to as PH diagrams. Enthalpy is the amount of heat in a substance, represented by the uppercase letter H . Specific enthalpy is the amount of heat per pound, represented by the lowercase h . PH diagrams show the relationships between a refrigerant's pressure, heat, temperature, volume, and state. The lines and scales used on PH diagrams represent the same thing on every PH diagram; each refrigerant just has different values. So once you understand the R-410A PH diagram shown in Figure 21-1, you can work with any other refrigerant's PH diagram.

21.3 PH DIAGRAM LINES AND SCALES

The key to understanding a PH diagram is learning what the different lines represent, the direction they run, and what units of measurement are used for each line.

Saturation Curve

The large hump in the middle of the PH chart is the saturation curve (Figure 21-2). Every point on or inside the saturation curve is saturated. The critical point is at the very top of the hump. The critical point is the pressure and temperature at which liquid and vapor are indistinguishable; refrigerant

cannot be saturated above the critical point. The left side of the curve is the saturated liquid line, and everything to the left of the saturation curve is subcooled. The right side of the curve is the saturated vapor line, and everything to the right of the curve is superheated. Everything inside the curve is saturated.

Constant Quality

The constant-quality area is the area inside the dome shape outlined by the saturated liquid and saturated vapor lines. The constant-quality lines start at the bottom and extend upward toward the critical point located in top center of the dome (Figure 21-3). These lines represent the percentage of vapor in the saturated refrigerant. Any point along the line marked 20 percent would have 20 percent vapor and 80 percent liquid. The lines run from 0 percent vapor at the saturated liquid line on the left, to 100 percent vapor at the saturated vapor line on the right. As you move from left to the right across these lines, there is more vapor and less liquid refrigerant. Moving from the right to the left increases the percent of liquid as compared to percent of vapor.

During the evaporation process in the evaporator, the percentage of vapor will increase and the percentage of liquid will decrease. This is shown as a left-to-right movement across the area. During the condensation process in the condenser, the percentage of vapor will decrease and the percentage of liquid will increase. This is shown as a right-to-left movement across the area (Figure 21-4).

Pressure

The pressure lines run horizontally from the right side to the left side of the diagram (Figure 21-5). The line spacing becomes closer together as they go up from the bottom. Each line is one-half the space of the previous line. If all the lines were drawn with the same scale units, by the time they got to the top of the diagram, they would be so close that it would appear as a single line. To make the pressure scale readable, the unit spacing changes from the bottom to the top.

Figure 21-4 The percentage of vapor refrigerant increases as the process moves from left to right, (blue arrow); the percentage of vapor refrigerant decreases as the process moves from right to left (red arrow).

Figure 21-5 The absolute pressure lines run horizontally.

The pressure scales shown on the right and left sides of PH diagrams are given in pounds per square inch absolute, psia. Notice that the scale changes three times from the bottom to the top. The bottom lines are drawn to represent increments of 1 psia, with every other line identified as 1, 2, 4, 6, 8, and 10 psia. The middle scale units are given in increments of 10 psia, with every other line identified as 10, 20, 40, 60, 80, and 100 psia. At the top, the scale changes to increments of 200 psia, with every other line identified as 200, 400, 600, 800, and 1,000. The pressure increments increase as you move up the PH diagram.

Absolute pressures are used so that the diagram's values can be universally used without regard to the cur-

rent weather or altitude. Subtract approximately 14.7 from these absolute pressures to get gauge pressure.

Enthalpy

The specific enthalpy lines are vertical lines going from top to bottom; the scale is shown along the top and bottom of the PH diagram. The units are given in BTU per pound of refrigerant, BTU/lb (Figure 21-6). Although the true enthalpy for a material starts from absolute zero, PH diagrams define their zero point to be the enthalpy of -40°F saturated liquid. Thus, it is possible to have a negative specific enthalpy on the PH chart. The specific enthalpy increases as you move

Figure 21-7 The constant temperature lines are not straight; they are semivertical in the liquid and vapor areas and horizontal in the saturated area.

from the left to the right and decreases moving from right to left.

Constant Temperature

The constant temperature lines start along the left top of the diagram and drop nearly vertically to a point where they intersect the saturated liquid line (Figure 21-7). At this point they travel horizontally across to the saturated vapor line, where they drop nearly vertically again. The temperature lines run horizontally inside the saturated region because the temperature of a saturated mixture stays the same as it changes state. All of the constant temperature lines run parallel as they make this zigzag path across the diagram. The temperature at any point on a constant temperature line is the same. For example, in Figure 21-7, you can follow the same 0°F temperature along the line down through the saturated liquid, across the constant quality area, and down through the saturated vapor.

constant entropy lines start at the bottom of the PH diagram and slope upward to the right (Figure 21-8). Although constant entropy lines can be shown across the entire PH diagram, many diagrams only show the entropy lines in the superheated vapor area. The refrigerant follows the constant entropy lines as it is compressed by the compressor.

Constant Volume

The constant volume lines are nearly horizontal lines that start at the saturated vapor line and gradually slope up to the right (Figure 21-9). These lines represent the change in density of the refrigerant at a constant pressure due to the increase in enthalpy and temperature. Follow the 60 psia line to the right starting at the saturated vapor, where it is about 0°F with about 120 BTU/lb enthalpy. At this point, 1 lb of refrigerant occupies about 1 ft³. At the right side of the PH diagram, following the same pressure line to about 360°F, this is at a point around 200 BTU/lb enthalpy. The same 1 ft³ volume now contains around 2 lb of refrigerant.

TECH TIP

Not all PH diagrams show the temperature lines in the saturated liquid area. Many PH diagrams' temperatures look more like Figure 21-1 than like Figure 21-7.

Constant Entropy

In refrigeration, entropy is defined as the ratio of the heat content of the refrigerant to its absolute temperature in degrees Rankine. On a PH diagram, entropy is expressed in terms of BTU per pound per degree (BTU/lb/R°). The

21.4 REFRIGERANT BLENDS

All refrigerants with a three-digit number whose number starts with 4 are zeotropic blends. A zeotropic blend is a mixture of two or more refrigerants that will physically separate when the refrigerant boils, changing the composition of the blend. Zeotropic refrigerant blends do not condense and evaporate at a single temperature. At any given pressure they have a bubble point and a dew point. The bubble point is the temperature where evaporation begins. It is when small gas bubbles start to form in the liquid. The dew point is the temperature where condensation begins. It is where small droplets of liquid first start to condense out of

Figure 21-9 Constant volume lines.

a gas. *Temperature glide* is the term used to describe the difference between the bubble point and dew point. Some zeotropes have a glide of 2°F or less, while others have a glide as high as 10°F. Figure 21-10 is a PH diagram for a high-glide blend, R-407C. The temperature lines (highlighted in blue) are higher on the left side of the constant-quality area than on the right side because evaporation starts at a slightly higher pressure with 100 percent liquid than condensation does with 100 percent vapor. The line passing through the saturated area represents the average temperature where a phase change occurs for the saturated mixture.

21.5 THERMODYNAMIC TABLES

One limitation of pressure-enthalpy diagrams is that obtaining precise data is difficult. PH diagrams allow a good overview of what is happening, but getting precise figures is difficult. For example, the pressure lines in Figure 21-1 go from 100 psia to 200 psia. Any pressures between those two must be interpolated. Refrigerant manufacturers publish tables of thermodynamic properties for each of the refrigerants that they sell. These allow much more precision when determining specific values. Figure 21-11 gives the

thermodynamic properties of saturated refrigerant R-410A, including pressure, temperature, enthalpy, and entropy for both liquid and vapor states. It is important to recognize that this chart is accurate only for saturated refrigerant. Charts are also published for superheated and subcooled refrigerant. Figure 21-11 can be used to find the pressure for any particular saturation temperature. Two pressures are listed—a liquid pressure and a vapor pressure—because R-410A is zeotropic. Since R-410A is a low-glide zeotrope, the pressure difference is slight. For example, the pressure of 10°F saturated refrigerant is approximately 76 psig. At 10°F, the saturated vapor has an enthalpy of 119.8 BTU/lb, while saturated liquid has an enthalpy of 16.2 BTU/lb.

21.6 REFRIGERATION-CYCLE PH DIAGRAM

PH diagrams can be used to show what happens in a refrigeration cycle, and a basic refrigeration cycle is plotted on the PH diagram in Figure 21-12. A refrigeration-cycle PH diagram contains four lines, each representing one of the four major components. Each line shows how the refrigerant changes in temperature, pressure, heat content, and state as it travels through the cycle.

Compressor

The line between points A and B in Figure 21-12 represents the compression process. The compressor line follows the entropy lines up. This line travels up because the refrigerant pressure is increased in the compressor and to the right because of the heat added by the compressor. Heat of compression is the amount of heat energy added by the compressor due to mechanical work. The discharge tem-

perature predicted by the enthalpy diagram is the theoretical discharge temperature based solely on heat added by mechanical work. In actual operation, the discharge temperature may be 20–35°F higher because of the heat added by the compressor motor in systems with hermetic or semi-hermetic compressors.

Condenser

The line between points B and E in Figure 21-12 represents the condenser. The line is horizontal because the pressure remains the same through all the condenser processes. The portion of the line from point B to the saturation curve represents the desuperheating portion of the condenser. Here, the refrigerant temperature drops until it reaches the saturation point. The refrigerant temperature remains the same from the intersection with the saturated vapor line until the intersection of the saturated liquid line. This portion of the process is called isothermal because the temperature remains the same while the refrigerant changes state from a gas to a liquid. At the saturated liquid line, the refrigerant is all liquid. The portion of the line between the intersection of the saturated liquid line and point E is the subcooling portion of the condenser. The liquid temperature drops in the subcooling section.

Metering Device

The line between point E and point G in Figure 21-12 represents the metering device. This line drops straight down because no heat is gained or lost in the metering device, but the pressure drops dramatically. The refrigerant increases in volume through the metering device. This is why one of the most common metering devices is called an expansion valve. This type of expansion without adding heat is

called adiabatic expansion. *Adiabatic* means without heat. The metering device line starts in the subcooled region and ends up in the saturated region of the PH diagram.

Evaporator

The line between point G and point A in Figure 21-12 represents the evaporator. It travels horizontally because the pressure remains the same in the evaporator. The line between point G and the intersection with the saturated vapor line represents the portion of the evaporator where refrigerant is changing state from a liquid to a gas. The temperature remains the same from point G to the intersection of the saturated vapor line because evaporation is an iso-

thermal process. This is where the vast majority of the heat is gained in the evaporator. All the liquid refrigerant has changed to vapor by the end of the evaporator. The portion between the intersection of the saturated vapor line and point A represents the superheat added to the refrigerant in the end of the evaporator.

21.7 SEVEN STAGES OF REFRIGERANT TRANSFORMATION

Now that the four lines representing the four major system components are in place, let's examine the entire process in more detail using a specific example. There are seven stages of refrigerant transformation within a refrigeration system: compressing, desuperheating, condensing, sub-cooling, expanding, evaporating, and superheating. Figure 21-13 shows a PH diagram of an air-cooled air-conditioning system using refrigerant R-410A operating with an outdoor ambient of 95°F and an indoor return air temperature of 80°F. The condenser temperature is 120°F–25°F warmer than ambient. The evaporator temperature is 40°F–40°F cooler than the return air temperature. The following explanation of each stage will refer to Figure 21-13.

Stage 1: Compression

At point A, the cool refrigerant vapor enters the compressor suction valve at 133 psia and 60°F. The compressor raises its temperature and pressure to approximately 175°F and 433 psia at point B. The temperature and pressure are raised by reducing the gas volume from 0.5 ft³/lb to 0.17 ft³/lb. The compressor line follows the constant entropy lines. Vertical lines drawn from points A and B to the constant enthalpy line show the heat added to the refrigerant by the compressor (Figure 21-14). The difference between the enthalpy at point A and the enthalpy at point B is the heat of compression. In this case, the heat of compression is 145 BTU/lb – 127 BTU/lb = 18 BTU/lb.

Stage 2: Desuperheating

Desuperheating, cooling off of the hot vapor refrigerant, occurs along the line between points B and C. Desuperheating decreases the sensible temperature and heat, but the pressure remains the same. Vertical lines drawn from points B and C to the constant enthalpy line show the heat removed from the refrigerant during desuperheating (Figure 21-15). The amount of desuperheating accomplished is the difference between the enthalpy of the vapor refrigerant at points B and C. In this case, 145 BTU/lb – 122 BTU/lb = 23 BTU/lb of heat removed by desuperheating the vapor refrigerant.

Stage 3: Condensing

Condensation begins after all the refrigerant superheat has been removed. Condensation of the refrigerant vapor into a liquid begins at point C, where the condenser line crosses the saturated vapor line. The temperature stops dropping; it is now 120°F. That is the saturated vapor-liquid temperature for 433 psia R-410A. Condensing continues to take place with no change in pressure or temperature until the

Figure 21-14 The heat of compression is the difference in the enthalpy at points A and B.

Figure 21-15 The condenser desuperheats the refrigerant between point B and points C, condenses the refrigerant between point C and D, and subcools the refrigerant between points D and E.

refrigerant reaches point D on the condenser line. Vertical lines drawn from points C and D to the constant enthalpy line would show the heat removed from the refrigerant during condensation (see Figure 21-15). In this case, $122 \text{ BTU/lb} - 62 \text{ BTU/lb} = 60 \text{ BTU/lb}$ of heat removed by condensing the refrigerant.

Stage 4: Subcooling

Subcooling is the lowering of a liquid's temperature below its saturated liquid pressure. Subcooling begins as the condenser line crosses the saturated liquid line between points D and E. If 10°F of subcooling occurs, the refrigerant temperature lowers to 110°F but the pressure remains at 433 psia. Vertical lines drawn from points D and E to the constant enthalpy line show the heat removed from the refrigerant during subcooling (see Figure 21-15). In this case, $62 \text{ BTU/lb} - 57 \text{ BTU/lb} = 5 \text{ BTU/lb}$.

Total Condenser Heat Rejection

Notice that the condenser must dissipate more heat than the evaporator absorbs—the heat of compression as well as the heat picked up in the evaporator. The total amount of heat rejected by the condenser is the total of desuperheating, condensing, and subcooling. That would be 23 BTU/lb desuperheating + 60 BTU/lb condensing + 5 BTU/lb subcooling = 88 BTU/lb total heat rejection. This can be found directly by subtracting the enthalpy at point E from the enthalpy of point B. In this case, $145 \text{ BTU/lb} - 57 \text{ BTU/lb} = 88 \text{ BTU/lb}$.

TECH TIP

Although subcooling accounts for a very small amount of heat compared to the rest of the process, it is still very important. Subcooling ensures that the refrigerant entering the metering device is 100 percent liquid. Any pressure drop in the liquid line between the condenser and the metering device will cause a saturated liquid to flash, creating gas bubbles. Bubbles of refrigerant vapor decrease the amount of refrigerant the metering device feeds, reducing the system's operating efficiency.

Stage 5: Expansion

The subcooled liquid refrigerant enters the metering device at point E with a pressure of 433 psia and a temperature of 110°F . It exits the metering device at point G as a saturated mixture of 30 percent vapor and 70 percent liquid with a pressure of 133 psia and a temperature of 40°F . No heat is added or removed from the refrigerant, so the enthalpy remains 57 BTU/lb (Figure 21-16). Expanding without adding heat is called adiabatic expansion. Point F is inside the metering device. This is where the refrigerant first starts to flash from a liquid to a gas because the pressure has dropped to the saturation point. The small amount of liquid flashing cools the remaining liquid.

Stage 6: Evaporating

Refrigerant enters the evaporator at point G. As this point, approximately 30 percent of the liquid refrigerant has flashed to vapor to cool the remaining liquid to 40°F . The $133 \text{ psia } 40^\circ\text{F}$ refrigerant flows into the evaporator, where it can begin to pick up heat. Along the line from point G to point H, heat is added to the refrigerant, causing it to evaporate, increasing the percentage of vapor to 100 percent. The 100 percent vapor point occurs at the saturated vapor line, point H. Note that the pressure of 133 psia and temperature of 40°F did not change, because this is an isothermal process. Point H is inside the evaporator.

Vertical lines drawn down from points G and H to the constant enthalpy line can be used to find the amount of heat that was added to the refrigerant as it changed from approximately 30 percent vapor to 100 percent vapor. In this case, $122 \text{ BTU/lb} - 57 \text{ BTU/lb} = 65 \text{ BTU/lb}$ heat gain through evaporation (Figure 21-17).

Stage 7: Superheating

From point H to point A, the pressure remains at 133 psia , but without any liquid refrigerant, the vapor refrigerant is superheated approximately 20°F . Point A is located at the point where the 133 psia line crosses the 60°F temperature line in the superheat section. The portion of the line from point H to point A shows the evaporator superheat. Vertical lines drawn from points H and A to the constant enthalpy line show the heat added to the refrigerant due to superheating (Figure 21-18). In this case, 127 BTU/lb

any particular load. This can then be used to determine the required compressor capacity.

21.8 CALCULATING REFRIGERATION EFFECT

The refrigeration effect is the difference in the enthalpy of the refrigerant entering the evaporator and the enthalpy of the refrigerant leaving the evaporator. The refrigeration effect is rated in BTU per pound of refrigerant (BTU/lb). Referring to Figure 21-19, the enthalpy of the refrigerant at point G, where the refrigerant enters the evaporator, is 57 BTU/lb, and the enthalpy of the refrigerant leaving the evaporator at point A is 127 BTU/lb. The refrigeration effect is then $127 \text{ BTU/lb} - 57 \text{ BTU/lb} = 70 \text{ BTU/lb}$.

The refrigeration effect can be used to determine the amount of refrigerant that needs to be circulated to meet

21.9 REFRIGERATION SYSTEM CAPACITY

Once we know how many BTUs a pound of refrigerant can pick up each time it passes through the evaporator, we can determine the pounds of refrigerant that must flow through the system to meet the system's load requirements. The amount of refrigerant that must be circulated can be calculated by dividing the system load in BTU per minute by the refrigeration effect. One ton of refrigeration is a rate of 200 BTU/min. For a refrigeration capacity of 1 ton, this system would need to circulate $(200 \text{ BTU/min}) / (70 \text{ BTU/lb}) = 2.9 \text{ lb/min}$. The required capacity per ton can be determined by dividing 200 BTU/min by the system's refrigeration effect as determined by the PH diagram.

Figure 21-19 The refrigeration effect is the difference in enthalpy between points G and A.

21.10 NET REFRIGERATION EFFECT

In their equipment performance standards, AHRI defines *net refrigeration effect* as

the rate of total heat absorption by the refrigerant, at stated evaporator conditions, of the complete refrigeration system. This effect is equal to the product of the refrigerant mass flow rate through the system and the enthalpy difference between the refrigerant vapor leaving the evaporator and the refrigerant liquid entering the liquid control device of the evaporator, BTU/h.

The refrigeration effect in the example was determined to be 70 BTU/lb, and the mass flow required 2.9 lb/min. Therefore, the net refrigeration effect is $70 \text{ BTU/lb} \times 2.9 \text{ lbs/min} = 203 \text{ BTU/min}$. The system's net refrigeration effect should match the heat load. (Note: The result of multiplying 2.9×70 is actually 203. The result should be 200, but compound error from rounding both the mass flow and enthalpy numbers yields the slight discrepancy.)

21.11 COMPRESSOR CAPACITY

For design conditions to be maintained within a refrigeration circuit, there must be a balance between the requirements of the evaporator coil and the capacity of the compressor. The compressor must have enough capacity to remove all the refrigerant that has vaporized in the evaporator and send the same weight of refrigerant vapor on to the condenser. If the compressor is too small, it will be unable to move all the vaporized refrigerant, and some of the vapor will remain in the evaporator. This will cause an increase in evaporator pressure and temperature and a decrease in system capacity.

Compressors are rated by the volume of gas they can move at particular low- and high-side pressures. The pressures the compressor must operate at are determined by the evaporating and condensing temperatures. The volume of gas to be moved is determined by the system capacity calculation. In this example, the amount of refrigerant to be circulated is 2.9 lb/min. The units of pounds per minute (lb/min) need to be turned into a volume: cubic feet per minute (ft^3/min). The enthalpy diagram shows that the volume of the refrigerant where it enters the compressor at point A is $0.5 \text{ ft}^3/\text{lb}$. Multiplying $0.5 \text{ ft}^3/\text{lb} \times 2.9 \text{ lb/min}$ gives the required total gas volume of approximately $1.5 \text{ ft}^3/\text{min}$. The compressor in this example must be able to move $1.5 \text{ ft}^3/\text{min}$ at a suction pressure of 133 psia and a head pressure of 433 psia to produce a capacity of 200 BTU/min. This is equivalent to 1 ton of refrigeration.

21.12 REFRIGERANT COEFFICIENT OF PERFORMANCE

The refrigerant coefficient of performance (RCOP) is a ratio of the efficiency of a specific refrigerant in the refrigeration cycle comparing the utilization of expended energy during the compression process in a ratio to the energy that is

absorbed in the evaporation process. RCOP is expressed as a ratio of the refrigeration effect to the energy used. RCOP may be calculated by dividing the refrigeration effect by the heat of compression: $\text{RCOP} = \text{refrigeration effect}/\text{heat of compression}$.

In Figure 21-19, the refrigeration effect would be the enthalpy of point A minus the enthalpy of point G: $127 \text{ BTU/lb} - 57 \text{ BTU/lb} = 70 \text{ BTU/lb}$ refrigeration effect. The heat of compression would be the enthalpy of point B minus the enthalpy of point A: $145 \text{ BTU/lb} - 127 \text{ BTU/lb} = 18 \text{ BTU/lb}$. The RCOP would then be $(70 \text{ BTU/lb})/(18 \text{ BTU/lb}) = 3.9$.

The RCOP for this refrigeration cycle is 3.9:1 (pronounced 3.9 to 1). That means 3.9 BTU of heat are removed for every BTU of heat added by the compressor. The less energy expended in the compression process, the larger the RCOP ratio of the system would be. When comparing refrigerants and operating conditions, the refrigerant and condition having the highest RCOP would be the best choice for energy efficiency.

21.13 PLOTTING AN OPERATING SYSTEM

Four measurements are all that are required to plot an operating system on a PH diagram: low-side pressure, high-side pressure, suction-line temperature, and liquid-line temperature. The system should be operating long enough for these readings to be stable before taking them. This example will use a system with R-410A, operating with a suction pressure of 116 psig, a head pressure of 417 psig, a suction-line temperature of 40°F , and a liquid-line temperature of 110°F .

Evaporator and Condenser Lines

The first step in plotting a refrigeration cycle on a PH diagram is to establish the condensing and evaporating lines. Take the system operating pressures and convert them to absolute pressure by adding 15. These pressures will be used to establish the evaporator and condenser lines. For example, with an R-410 system operating with pressures of 116 psig on the low side and 417 psig on the high side, the absolute pressures would be 131 psia and 432 psia. Draw a horizontal line across the saturation curve at 131 psia for the evaporator line and at 432 psia for the condenser line. Do not worry about exactly where the lines should start and stop; just make sure they go all the way across the saturation curve on both sides. Figure 21-20 shows the evaporator line in blue and the condenser line in red.

Compressor Line

Measure the suction-line temperature entering the compressor. Find where the evaporator line crosses this suction-line temperature in the superheated area. In our example, this is 60°F . This is where the compressor line starts. Follow the entropy lines up until they cross the condenser line. This is where the compressor line ends. Figure 21-21 shows the compressor line in green.

Figure 21-20 The evaporator line is drawn in blue at 131 psia; the condenser line is drawn in red at 432 psia.

Figure 21-21 The compressor line, drawn in green, starts where the evaporator line intersects the 60°F temperature line and follows the entropy lines up to the condenser line.

Metering Device Line

Measure the temperature of the liquid line entering the metering device. Follow the condenser line until it crosses this liquid-line temperature in the subcooled area. In our example, this is 110°F. This is where the

metering device lines starts. Draw a line straight down until it crosses the evaporator line. This is where the metering device line ends. Figure 21-22 shows the metering device line in purple. Figure 21-23 shows the completed plot of the cycle with the evaporator and condenser lines cleaned up.

Figure 21-22 The metering device line, shown in purple, starts where the condenser line intersects the 110°F temperature line and drops straight down to the evaporator line.

UNIT 21—SUMMARY

A refrigerant pressure-enthalpy diagram, called a PH diagram, shows the relationship of all the physical characteristics of a refrigerant, including pressure, temperature, heat, volume, and state. PH diagrams can be used to determine a system's refrigeration capacity, the amount of refrigerant that must be circulated, the amount of heat absorbed by the evaporator, the amount of heat rejected by the condenser, or the required compressor capacity. PH diagrams

have a large hump in the middle called the saturation curve. Everything inside the curve is a saturated mixture of liquid and gas. Everything to the right of the curve is superheated gas, and everything to the left of the curve is subcooled liquid. Enthalpy is the amount of heat in something; specific enthalpy is the amount of heat per pound. The specific enthalpy lines are vertical and marked in BTU/lb. The pressure lines are horizontal lines that are marked in absolute pressure, psia. The temperature lines are nearly vertical in the vapor and liquid areas but horizontal in the saturated area, giving them a zigzag appearance. The temperature remains

constant when heat is added inside the saturation curve. This is called an isothermal process. The refrigeration cycle is shown with four lines. A horizontal line at the bottom shows the evaporator, and a horizontal line at the top shows the condenser. They are connected by the compressor line, which follows the entropy lines up. Entropy is the amount of heat per pound per degree in the refrigerant and is measured in BTU/lb/°F. No heat is added or lost when the refrigerant passes through the metering device. This is why the metering device is shown as a vertical line dropping straight down from the condenser line to the evaporator line.

UNIT 21—REVIEW QUESTIONS

1. List the refrigerant characteristics that are shown on a pressure-enthalpy diagram (PH).
2. What is the saturation curve?
3. Where are the pressure lines, and how are they marked?
4. Define *enthalpy*.
5. Explain the difference between enthalpy and specific enthalpy.
6. Where are the specific enthalpy lines, and how are they marked?
7. Why are the temperature lines horizontal inside the saturated curve?
8. What are the constant quality lines?
9. As you move to the right or left along a constant pressure line in the saturated liquid area, what happens to the temperature?
10. As you move to the right or left along a constant pressure line, what happens to the specific enthalpy?
11. As you move up or down along a constant enthalpy line, what happens to the pressure?
12. As you move up along a constant enthalpy line in the constant quality area, what happens to the temperature?
13. In refrigeration, how do we define *entropy*?
14. Why does some of the refrigerant liquid flash-vaporize in the metering device?
15. At what point in the refrigeration cycle does the last of the liquid vaporize?
16. What happens to the refrigerant pressure during desuperheating?
17. When does liquid refrigerant first begin forming in the condenser?
18. What is subcooling?
19. How much heat enters the refrigerant in the metering device when some of it flashes to a vapor, cooling the remaining liquid to the evaporator temperature?
20. What can bubbles of refrigerant vapor do to the metering device's operating efficiency?
21. When does a refrigerant pick up most of the heat as it circulates through a system?
22. Define *adiabatic*.
23. Define *isothermal*.
24. Explain how a system's refrigeration effect can be determined.
25. Determine the refrigeration effect of the following system: the liquid entering the evaporator has an enthalpy of 64 BTU/lb, and the vapor leaving the evaporator has an enthalpy of 121 BTU/lb.
26. What is the net refrigeration effect for the system in question 25 if the system is circulating 4 lb of refrigerant each minute?
27. When drawing a PH diagram of an operating system, how is placement of the condenser and evaporator lines determined?
28. When drawing a PH diagram of an operating system, how is placement of the compressor line determined?
29. When drawing a PH diagram of an operating system, how is placement of the metering device line determined?
30. Why is the condenser line wider than the evaporator line in a PH diagram of a refrigeration cycle?
31. How can a PH diagram be used to select the system compressor?
32. How can a PH diagram be used to determine the heat of compression?
33. How can a PH diagram be used to determine the RCOP for a particular system?
34. How many pounds of refrigerant must flow through a 4-ton evaporator each minute if each pound has an enthalpy of 50 BTU/lb?
35. What will happen in the evaporator if the compressor capacity is not large enough to remove all of the vapor?
36. On a blank sheet of paper, sketch a typical PH diagram for a refrigeration system. You do not need to duplicate all the scales on the PH diagram. Just show the saturation curve and the four cycle lines.

UNIT 22

Refrigerant Safety

OBJECTIVES

After completing this unit, you will be able to:

1. demonstrate how to obtain and read a refrigerant MSDS.
2. apply proper first aid in the event of a refrigeration accident.
3. explain the refrigerant safety rating system.
4. list the safety hazards associated with handling refrigerants.
5. explain the difference among nonrefillable, refillable, and recovery refrigerant cylinders.
6. list the personal protection equipment (PPE) for handling refrigerant.
7. properly dispose of a DOT 39 refrigerant cylinder.
8. explain the difference among a safety relief valve, a rupture disk, and a fusible plug.
9. describe the operation of machinery room refrigerant sensors.

22.1 INTRODUCTION

The refrigeration machines of the early 1900s were the forerunners for today's advanced food processing, product storage, and air-conditioning systems. Unfortunately, these first machines used refrigerants that were flammable, toxic, and highly reactive. In the late 1920s, Thomas Midgley began work to develop nontoxic, nonflammable refrigerants referred to as fluorocarbons. Little did anyone realize at the time that most of these "safe" refrigerants also contained chlorine (CFCs and HCFCs) and were slowly damaging the earth's protective ozone layer.

To reverse this trend, the phase-out of these chlorinated refrigerants has led to the development of totally new refrigerants as well as the increased usage of longstanding refrigerants such as ammonia. This has resulted in a potentially large field of refrigerants that you must become familiar with. Fortunately, refrigerant-specific information is readily available. The specific hazards of each type of refrigerant can be determined by referring to its MSDS. Also, refrigerant safety ratings designated by ANSI/ASHRAE Standard 34-2010 help to provide a simple breakdown for toxicity and flammability.

22.2 MATERIAL SAFETY DATA SHEETS (MSDS) AND PERSONAL PROTECTION EQUIPMENT (PPE)

The first place to begin with any new refrigerant is to review the MSDS (Material Safety Data Sheet). An MSDS will accompany a newly purchased refrigeration cylinder if requested. Another way to access an MSDS is to download it from the Internet, as these are often made available by refrigerant manufacturers. It is advisable to have a reference copy available and on hand for each refrigerant type being used.

Material Safety Data Sheets

Although the refrigerant MSDSs will vary slightly depending on the manufacturer, they all contain similar information.

The first section of the MSDS, Chemical Product and Company Identification, will have an emergency overview and call number. Section 3, Hazards Identification, provides a listing of potential health hazards to the skin and eyes and from inhalation. Section 4, First Aid Measures, includes first-aid measures for the skin, eyes, inhalation, and ingestion, along with advice for the physician. This information will be important if an accident does occur and may need to be referred to quickly. This is why it is important to review the MSDS beforehand so that you are not scrambling for information at the time of an accident.

Just as important in taking the right steps when an accident occurs is trying to prevent an accident in the first place. Section 8, Exposure Controls/Personal Protection, lists the exposure controls and personal protection equipment required for handling refrigerants. Items such as gloves for skin protection, goggles for eye protection, and breathing apparatus for respiratory protection are listed, along with any additional recommended special equipment.

Other important sections include 5, 6, and 7, Firefighting Measures, Accidental Release Measures, and Handling and Storage. Section 9, Physical and Chemical Properties, lists information such as vapor pressure and boiling point. The MSDS is a valuable reference that should be made available to anyone who is handling refrigerants or servicing refrigeration systems.

Personal Protection Equipment

It is important to protect yourself whenever working with refrigerants. Hoses sometimes fail and fittings sometimes leak, which could cause refrigerant to come in contact with your skin or eyes. Approved safety glasses, marked Z87 on the frame or lens, are impact and shatter resistant and should be worn whenever working with refrigerants. Chemical splash goggles provide for even further protection, and some are designed to be worn over prescription glasses. Face shields can be worn with safety glasses, or goggles and can be used when maximum protection is required.

Protective gloves should be worn whenever handling refrigerants. They should not only protect against exposure but also resist physical hazards such as abrasion and cuts. The thickness and therefore the amount of dexterity the glove allows is important because a bulky glove may be inadequate for the job required. Glove size and length should also be considered, as longer gloves will protect more of the arm. Proper-fitting gloves are important because tight gloves cause fatigue and large gloves have loose finger ends, which make work more difficult. Generally, leather gloves will provide adequate protection for common refrigeration work. If prolonged contact with liquid or gas is anticipated, then insulated gloves constructed of neoprene, nitrile, Viton, butyl, or polyvinyl alcohol (PVA) should be worn. Some manufacturers offer glove compatibility charts to help you select the best glove for the refrigerant you will be handling.

A self-contained breathing apparatus (SCBA) is a device worn by rescue workers, firefighters, and others to provide breathable air in an “immediate danger to life and health” (IDLH) atmosphere. The term *self-contained* means that there is a high-pressure tank and regulator, and therefore a long supply hose from an external source is not required. An SCBA is very similar to an underwater scuba (self-contained underwater breathing apparatus) tank. Machinery spaces that have the potential for large refrigerant spills must meet special mechanical ventilation requirements because the refrigerant will displace the oxygen in the space. If a refrigerant spill occurs, then a Mine Safety and Health Administration/National Institute for Occupational Safety and Health (MSHA/NIOSH)-approved SCBA must be worn upon entering the space whenever the refrigerant concentration levels are suspected to be above permissible limits.

22.3 FIRST AID

The first steps taken to help someone in distress can often be the most important to ensure his or her safety. If an accident does occur, time will pass before trained medical personnel arrive on site. By understanding the hazards involved when working with refrigerants, you will be better prepared to provide basic medical care until help arrives.

Frostbite

Of course, all refrigerants can be cold. Letting liquid refrigerant come into contact with exposed skin can cause “burns.” Immediately after the incident, the skin will just look irritated and red. In one hour after the exposure, blisters will start to appear and the skin will start to swell and puff up. In bad cases, the outer skin comes off and the area is treated like a third-degree burn. Technicians should wear safety goggles to protect their eyes and neoprene-lined gloves to protect their hands when handling refrigerants.

If refrigerant comes into contact with the skin, the area should be flushed with water. If there is evidence of frostbite, then bathe (do not rub) with lukewarm (not hot) water. If water is not available, cover the affected area with a clean, soft cloth. If refrigerant comes into contact with the eyes, immediately flush with large amounts of water for at least fifteen minutes with warm (not hot) water.

SAFETY TIP

HFC R410a boils at -62.9°F at atmospheric pressure. Skin exposed to a direct liquid stream for only a minute can receive severe frostbite that acts like a second- or third-degree burn. Keep your hands out of streams of liquid refrigerant. Refrigerant can be replaced, but your hands cannot!

Inhalation

If refrigerant has been inhaled, then immediately remove the victim from the space to fresh air. If breathing has stopped, give artificial respiration. Use oxygen as required, provided there is someone qualified to administer it. At high levels of inhalation, cardiac arrhythmia may occur. Because of the possible disturbances of cardiac rhythm, catecholamine drugs, such as epinephrine (adrenaline), should not be given.

Asphyxiation

Most refrigerants are heavier than air and will displace the oxygen in a room. Because of this, releasing large quantities of nontoxic refrigerant into a confined machinery space can cause asphyxiation (suffocation). Most of these refrigerants are odorless, so there may be no outward signs other than the victim becoming lightheaded. Under such circumstances, unconsciousness can occur quickly and with little to no warning. Coming to someone’s aid in such circumstances requires good judgment. You do not want to rush into the space to rescue someone and become the second victim. First start the ventilation system and use a MSHA/NIOSH-approved SCBA to enter the space if the refrigerant concentration levels are still excessive.

TECH TIP

All commonly used refrigerants except ammonia (R-717) and water (R-718) are heavier than air.

22.4 AMMONIA

More than 80 percent of all ammonia produced is used for agricultural purposes. Less than 2 percent is used for refrigeration, and it must be 99.98 percent pure dry (anhydrous) ammonia to prevent freeze-up. Ammonia attacks copper, zinc, and alloys of copper and zinc. However, ammonia can be safely used as a refrigerant provided the system is properly designed, constructed, operated, and maintained. Unlike most refrigerants, ammonia is lighter than air and rises. Pure ammonia vapors are a fire and explosion hazard at concentration ranges of approximately 15–28 percent. When mixed with lubricating oils, its flammable range is increased even further. Table 22.1 provides information on the exposure limits and health risks for ammonia.

Table 22-1

Concentration	Effect of Ammonia
5 ppm	Odor threshold
25 ppm	TWA exposure limit and noticeable odor
35 ppm	Short-term exposure limit
50 ppm	Permissible exposure limit (PEL), detectable by most people
140 ppm	Eyes irritated, strong odor
300 ppm	Immediately dangerous to life and health (IDLH)
400 ppm	Major throat irritation
700 ppm	Coughing, severe eye irritation may lead to loss of sight
1,700 ppm	Convulsive coughing, serious lung damage, possible death
2,000 ppm	Skin blisters and burns within seconds, no exposure permissible
5,000 ppm	Respiratory spasms, rapidly fatal

First-aid treatment for ammonia exposure is similar to that for most refrigerants. If the possibility of exposure above 250 ppm exists, use a MSHA/NIOSH-approved SCBA with a full face piece operated in a pressure-demand or other positive-pressure mode. Bring the victim to fresh air and flush the affected parts with warm water. Eyes affected by ammonia close involuntarily, so the eyelids must be held open. Clothes saturated with ammonia may freeze to the skin. While still clothed, the victim should immediately get under a shower. Remove clothes only after they are thawed out and can be freely removed from the frozen areas.

TECH TIP

Ammonia is widely used in large industrial refrigeration systems because it has a high net refrigeration effect and low impact on the environment. However, most fatal refrigeration accidents have resulted from the sudden release of ammonia. OSHA statistics show that from 1984 through 2006, there were 224 accidents and 50 fatalities involving the release of ammonia in the United States.

22.5 ANSI/ASHRAE STANDARD 34-2010

ANSI/ASHRAE Standard 34-2010, Designation and Safety Classifications of Refrigerants, addresses refrigerant safety. Refrigerants are grouped by their toxicity and flammability. Each refrigerant is assigned a safety rating consisting of a letter and a number. The letter *A* identifies refrigerants with lower toxicity, and the letter *B* identifies refrigerants with higher toxicity. The numbers 1–3 that follow the letters are used to indicate the flammability of the refrigerant. The number 1 would indicate a low flammability, while the number 3 would indicate a high flammability. As an example, A1 would indicate low toxicity and low flammability. A3 would indicate low toxicity and high flammability. B3 would indicate high toxicity and high flammability (Table 22.2).

CODES AND STANDARDS

ANSI/ASHRAE Standard 34-2010, Designation and Safety Classification of Refrigerants, describes a shorthand way of naming refrigerants and assigns safety classifications and refrigerant concentration limits based on toxicity and flammability data.

Toxicity

Almost anything can be toxic in high enough concentrations. For example, the air we breathe is approximately 78 percent nitrogen. However, breathing 100 percent nitrogen will cause asphyxiation. *Toxicity* is defined as the ability of a refrigerant to be harmful or lethal due to acute or chronic exposure by contact, inhalation, or ingestion. (Section 11 of a refrigerant’s MSDS provides toxicological information.)

Table 22-2

Safety Group		
Higher Flammability ↑	A3	B3 Toxic & Flammable
Lower Flammability ↑	A2 A2L	B2 B2L
No Flame Propagation ↑	A1 Non-toxic & Non-flammable	B3
Increasing Toxicity →		

The maximum safe exposure level in parts per million by volume is called the threshold limit value (TLV). The time weighted average (TWA) concentration for a normal eight-hour day, forty-hour week that is safe without any adverse effect is referred to as the threshold limit value–time weighted average (TLV-TWA). This is often commonly expressed as the occupational exposure limit (OEL).

TECH TIP

Parts per million (ppm) can sound confusing because it is difficult to comprehend a number as large as 1 million. If you started counting nonstop from 1 to 1 million, it would take you over 11½ days to finish. Ammonia has an occupational exposure limit of 25 ppm, which is equivalent to less than ½ minute of an 11½-day count. Another way to look at it is that 25 ppm would be equivalent to .0025 percent.

A highly toxic refrigerant would require a small amount as measured in ppm to reach the OEL, while a nontoxic refrigerant would require a much higher value. As an example, nontoxic R-134a has an OEL of 1,000 ppm, while toxic ammonia has an OEL of 25 ppm. Only a small amount of ammonia needs to be released to reach the threshold limit. Since this value is based on an average person, a small percentage of people may experience discomfort at concentrations below the TLV depending on their health and medical background.

The permissible exposure level (PEL), which is similar to OEL, is based upon a TWA as set by the Occupational Safety and Health Administration (OSHA). The safety group rating “A” is used to designate low-toxicity refrigerants having a PEL of 400 ppm by volume or greater. Safety group rating “B” designates high-toxicity refrigerants having a PEL of less than 400 ppm by volume. Type “B” refrigerants are prohibited in many applications by building and safety codes.

Most common CFC, HCFC, and HFC refrigerants are listed as type “A” refrigerants. One notable exception is R-123, which is a low-pressure HCFC refrigerant used in large, low-pressure chillers. It is considered a type “B” refrigerant. Many older refrigerants are type “B,” including ammonia, sulfur dioxide, and methyl chloride. An example of different refrigerants and their safety group classifications are provided in Table 22.3. Note that this rating system does not distinguish between refrigerants that will kill you in a few minutes and refrigerants like HCFC-123 that will cause some physical distress when you are exposed for eight hours a day, forty hours a week.

TECH TIP

Refrigerant toxicity safety ratings are normally based on the permissible exposure level (PEL) set by OSHA. Chemical manufacturers may also publish similar recommendations, such as occupational exposure limit (OEL), acceptable exposure level (AEL), and industrial exposure limit (IEL), generally for substances for which PEL has not been established.

Flammability

A refrigerant’s flammability is listed as type 1, nonflammable; type 2, somewhat flammable; or type 3, very flammable. There is also one optional subclass, type 2L. These ratings are based on the refrigerant’s lower flammability limit (LFL), the heat of combustion, and an optional burning velocity measurement. Refrigerant flammability for single-

compound refrigerants is based on their worst case of formulation for flammability (WCF). The rating for refrigerant blends is based on the worst case of fractionation for flammability (WCFF). (Sections 5 and 9 of a refrigerant's MSDS provide information on the refrigerant's flammable properties.)

The LFL is the minimum concentration in ppm of flammable liquid vapor in air that will support the propagation of flame upon contact with an ignition source. A liquid vapor/air mixture can be too lean (not enough, low ppm) to burn below the LFL or too rich (too much, high ppm) to burn above the upper flammable limit (UFL). As an example, ammonia is flammable between the concentration limits of 15 and 28 percent. Below 15 percent, the ammonia mixture is too lean to burn, and above 28 percent the mixture is too rich to burn.

Nonflammable type 1 refrigerants will not ignite and will not support combustion, which means they do not have an LFL limit. An example of a single-compound refrigerant type 1 rating is R-134a, based on its WCF. The UFL is not considered for flammability ratings.

Refrigerants listed as type 2 are somewhat flammable and in the proper concentrations (not too lean or too rich) will ignite when exposed to a flame. However, they will not continue to burn when the flame is removed. An example of a single-compound refrigerant type 2 rating is R-717, ammonia. It has an LFL of 167,000 ppm by volume. Concentrations of ammonia above this limit but below the UFL can be ignited.

A refrigerant with a 2L rating would have a slower burning velocity, meaning the flame would not burn as fast as a refrigerant classified with a type 2 rating. Some refrigerant manufacturers may choose to apply for this optional category, which would indicate a better safety rating than type 2.

Refrigerants with a flammability rating of 3 will ignite and support combustion. An example of a single-compound refrigerant type 3 rating is R-290, propane. It has an LFL of 21,000 ppm per volume. As compared to ammonia (167,000 ppm by volume), it would take far less propane, almost 8 times less, to support a flame.

Safety Rating for Zeotropes (Blends)

Azeotropic refrigerants are rated just like pure compounds because they do not separate when they boil. However, zeotropic refrigerants can fractionate (separate) when they boil. This raises the possibility that a mixture's characteristics can change. For this reason, zeotropic refrigerants are assigned a safety group classification based on the worst case of fractionation.

The worst case of fractionation for flammability (WCFF) is defined as the composition during fractionation that results in the highest concentration of the flammable component(s) in the vapor or liquid phase. So if one part of a three-part blend vaporizes, and that part is the most flammable, the refrigerant will be assigned a rating based on it even though the other two parts may be less flammable or maybe not even flammable at all.

The worst case of fractionation (WCF) for toxicity is defined as the composition during fractionation that results in the highest concentration of the component(s) in the vapor or liquid phase for which the TLV-TWA is less than 400 ppm by volume. Remember, more toxic refrigerants have lower

allowable ppm concentrations, therefore less than 400 ppm means more toxic.

22.6 CHEMICAL INTERACTIONS

There are safety concerns that arise from the interaction of refrigerants and their surroundings. (Section 10 of a refrigerant's MSDS provides information on the refrigerant's stability and reactivity.) For example, chlorofluorocarbons and hydrochlorofluorocarbons (CFCs and HCFCs) are not flammable. However, they chemically decompose when exposed to flames or very high temperatures, releasing their chlorine and fluorine. This creates highly irritating and potentially toxic gases, including chlorine gas, fluorine gas, and phosgene gas.

SAFETY TIP

Never braze tubing or do any hot work on systems that contain HCFCs and CFCs without first evacuating the lines, because these refrigerants will chemically decompose and produce toxic gases.

HCFCs and HFCs can react violently with some metals. HCFCs should never be exposed to magnesium. HFCs should not be allowed to come into contact with freshly abraded aluminum. Aluminum that has been recently ground up can react violently with HFCs. Some HFCs are flammable under high pressure with large concentrations of oxygen. Of course you should never put oxygen or compressed air into any refrigeration system. The oxygen under pressure can cause an explosion when mixed with the refrigerant oil.

22.7 REFRIGERANT STORAGE CYLINDERS

Refrigerants need to be transported and stored safely. Metal cylinders are specifically designed for this purpose. They come in different sizes and are often color coded. The cylinders will contain both liquid and vapor refrigerant under pressure, so they will be equipped with some form of burst protection. Due to the potential hazards encountered in the storage and handling of refrigerants, cylinders must meet regulatory requirements. The three basic types of refrigerant cylinders are as follows:

- Nonrefillable refrigerant cylinders
- Refillable refrigerant cylinders
- Recovery cylinders

A typical recovery cylinder is shown in Figure 22-1.

CODES AND STANDARDS

The regulations for nonrefillable refrigerant cylinders are specified in Title 49, Code of Federal Regulations (CFR), Section 178.65, Specification 39.

Figure 22-1 Refrigerant recovery cylinder in use.

22.8 DOT 39 NONREFILLABLE CYLINDERS (DISPOSABLE)

As the name suggests, the nonrefillable refrigerant cylinder is only filled one time, by the refrigerant manufacturer (Figure 22-2). The regulations for these cylinders are specified in Title 49, Code of Federal Regulations (CFR), Section 178.65, Specification 39. It should never be refilled by anyone with anything, not even the refrigerant manufacturer. Disposable

Figure 22-2 Nonrefillable refrigerant.

Figure 22-3 Nonrefillable cylinders have a check valve in the stem to prevent flow-back into the cylinder.

cylinders come with check valves built in that make refilling the cylinders nearly impossible, because the check valves prevent flow-back into the cylinder (Figure 22-3).

These cylinders are nonrefillable for a reason: they are not built to last as long as refillable cylinders and cannot withstand the same rigors as an approved recovery cylinder. The number-one reason for not refilling disposable cylinders is to keep all your body parts firmly attached. The number-two reason not to refill a disposable cylinder is that the potential penalty for refilling and transporting a nonrefillable cylinder is now up to a \$500,000 fine and five years in prison (Figure 22-4). This regulation is a Department of Transportation rule. It is designed to keep the highways safe, and it is enforced. (Section 14 of a refrigerant's MSDS provides transport information.)

To prevent disaster, disposable cylinders should not be stored or used in temperatures exceeding 125°F. All refrigerant cylinders are rated for a maximum recommended service pressure. Most DOT 39 disposable cylinders have a service pressure of 260 psig. Disposable cylinders for use

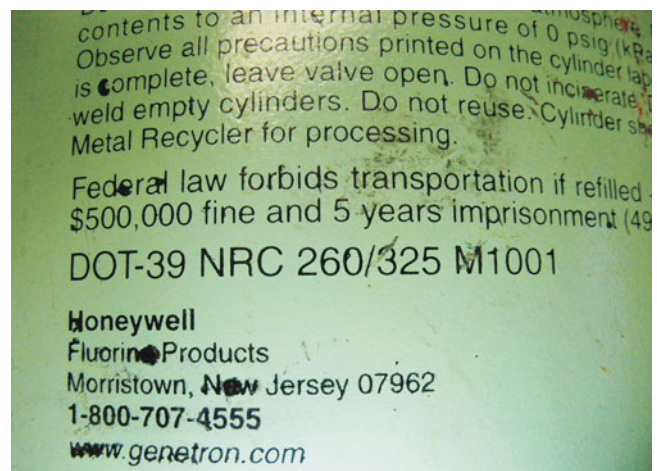

Figure 22-4 The penalty for refilling and transporting a nonrefillable cylinder is a \$500,000 fine and/or five years imprisonment.

Figure 22-5 Pressure ratings of DOT 39 cylinders.

Refrigerant	Service Pressure	Test Pressure	Burst Pressure
R-410A	400 psig	500 psig	1,000 psig
All others R-134a, R-22, etc.	260 psig	325 psig	650 psig

with R-410A have a service pressure of 400 psig. These pressures correspond to a temperature of 120°F for saturated refrigerant. At the maximum recommended cylinder temperature of 125°F, these pressures increase to 278 psig and 447 psig, respectively. They are tested at the factory at 125 percent of their rated service pressure and are supposed to have a minimum burst pressure of 250 percent of their rated service pressure. Figure 22-5 lists the service pressure, test pressure, and burst pressure for both types of DOT 39 disposable cylinders.

DOT 39 disposable cylinders have a frangible disk built into them to prevent pressures from reaching the bursting point of the cylinder (Figure 22-6). These disks look like knockouts in electrical boxes. A restriction on the other side of the disk limits the amount of flow out of the hole to prevent turning the cylinder into a missile (Figure 22-7).

Figure 22-6 Frangible disk on nonrefillable DOT 39 cylinder.

Figure 22-7 Flow-limiting orifice on the inside of the cylinder underneath the frangible disk

SAFETY TIP

The frangible disk cannot protect the cylinder against all hazards. Heating the cylinder with a torch, or leaving the cylinder in the weather for extended periods of time, can create new weak spots that can lead to a violent cylinder rupture.

Disposable Cylinder Recycling

The cylinder cannot be reused, but the metal may be recycled. Any remaining refrigerant cannot be vented to atmosphere but instead must be recovered using proper recovery equipment and procedures. After all remaining refrigerant has been removed, the cylinder valve may be opened. A metal chisel can be placed on the inside serration of the rupture disk located on the shoulder of the tank. A hammer can be used to lightly tap the chisel to pierce the rupture disk open. After the rupture disk has been completely removed, a large circle is to be drawn with permanent marker around the open rupture disk and labeled EMPTY. The tank can then be recycled along with other steel recyclables at a local steel recycling center.

22.9 REFILLABLE REFRIGERANT CYLINDERS

The name says it all: refillable cylinders are intended to be refilled. However, only the owners of the cylinders or their agent may refill them. Refillable cylinders are large cylinders with water capacities of 123 lb or more. Refrigerant can be purchased in a large cylinder as shown in Figure 22-8. The customer generally pays a deposit on this cylinder when purchasing the refrigerant. When the cylinder is empty it is returned to the wholesaler. It is important to note that the refrigerant company still owns the cylinder. This means that the field service technician is not authorized to refill it.

CODES AND STANDARDS

The regulations for refrigerant recovery cylinders are specified in Title 49, Code of Federal Regulations (CFR). Recovery cylinders of the DOT 4BA type are covered in Section 178.51.

22.10 RECOVERY CYLINDERS

The primary differences between a refillable cylinder and a recovery cylinder are size and ownership. Recovery cylinders are normally available in water capacities of 27 lb and

Figure 22-8 150-lb net weight cylinder of CFC R-114. Note the tag lists a deposit fee for the cylinder.

47 lb. Refillable cylinders and recovery cylinders are regulated by the DOT in Title 49, Code of Federal Regulations (CFR), covering transport of hazardous materials. This is an extensive set of rules covering many things, and refrigerant cylinders are only a very small part of this regulation. The primary hazard refrigerant cylinders pose is rupture.

Recovery Cylinder Service Pressure

Cylinders are marked with the particular DOT specifications for that cylinder. The numbers and letters immediately following the letters DOT describe how the cylinder is made while the last group of numbers describes the cylinder service pressure. For example, a DOT-4BA-350 recovery cylinder is a welded or brazed steel cylinder with a recommended service pressure of 350 psig (Figure 22-9). This

Figure 22-9 This specification shows that the service pressure for this recovery cylinder is 350 psig.

Figure 22-10 Refrigerant recovery cylinder cut in half showing the liquid valve tube.

is the most common specification for refrigerant recovery cylinders. There are also some DOT-4BA-260 and DOT 4BA-400 cylinders in use. These cylinders have recommended service pressures of 260 psig and 400 psig, respectively. Figure 22-10 shows the inside of a recovery cylinder that has been cut in half.

Pressure-Relief Valve

Recovery cylinders have an automatic pressure-relief valve built in that opens at 150 percent of the rated cylinder service pressure (Figure 22-11). The outlet of the relief valve should never be plugged or obstructed by anything. These valves reset once the pressure in the cylinder has dropped to a safe level.

Figure 22-11 Pressure-relief valve on recovery cylinder.

Figure 22-12 This recovery cylinder can hold 47.7 lb of water.

Recovery Cylinder Markings

In addition to the DOT specifications and service pressure markings, there are other crucial markings stamped on the recovery cylinder, including the following:

- Water capacity
- Tare weight
- Date of manufacture
- First retest date
- Most recent test date
- Last allowable retest date

The water capacity is equal to the weight of an equivalent amount of water required to completely fill the cylinder (Figure 22-12). The tare weight is the weight of the empty cylinder (Figure 22-13). These pieces of information are used to calculate how much refrigerant the cylinder can safely hold. This topic will be covered in detail in Unit 28, Refrigerant Management.

CODES AND STANDARDS

The regulations for requalification of refrigerant recovery cylinders are specified in Title 49, Code of Federal Regulations (CFR), Section 180.205.

Recovery Cylinder Requalification (Retest)

AHRI Guideline K-2009 requires that refillable cylinders used to recover refrigerant must be inspected and hydrostatically tested a minimum of once every five years in accordance with Title 49 CFR, Section 180.201. The date of manufacture and the first retest date are stamped onto every cylinder (Figure 22-14). The first retest date gives the month and year that a cylinder must be requalified. If the first requalification date has not yet arrived, the cylinder should be still on its first five years. Note that the five years starts when the cylinder is made, not when it is purchased. A cylinder that was made two years ago can only be used for another three years before getting requalified, even if it has been

Figure 22-13 This recovery cylinder weighs 28.1 lb when empty.

sitting on the shelf in the store. If the first retest date has already passed, the cylinder should not be used unless it was retested. If it was retested, the date that it was retested should be stamped on the cylinder. If the date was less than five years ago, the cylinder should be safe to use.

Some cylinders also have a last permissible use date (Figure 22-15). These are commonly known as 5 + 5 cylinders. They can only be requalified one time. These cylinders may not be used past the last permissible use date.

CODES AND STANDARDS

AHRI Guideline N-2008 and Guideline K-2009 address suggested colors for most refrigerant containers and recovery cylinders.

Cylinder Color and Labeling

AHRI Guideline N-2008, Guideline for Assignment of Refrigerant Container Colors, addresses suggested colors for most refrigerant containers except for recovery cylinders (Figure 22-16). AHRI Guideline K-2009, Guideline for Containers for Recovered Non-Flammable Fluorocarbon

Figure 22-14 This recovery cylinder was manufactured July 1998.

Figure 22-15 This 5 + 5 cylinder was manufactured in March 1997 and retested in March 2002, and the last permissible refill date was March 2007.

Refrigerants, specifies that recovery cylinders all be painted gray with a yellow top regardless of the type of refrigerant in the cylinder (Figure 22-17). This allows the recovery cylinders to be fairly generic and used with a variety of different types of refrigerants. Of course these cylinders must be clearly labeled with the type of refrigerant they contain since cylinder color cannot be relied upon to identify them. The only thing the technician knows for sure by the color is that refrigerant in a gray and yellow cylinder is not new.

The Environmental Protection Agency (EPA) requires that any cylinder containing a recovered refrigerant that is classified as a Class I (CFC) or Class II (HCFC) must display a warning statement: *WARNING: Contains [insert refrigerant type, such as R-22 etc.], which harms public health and environment by destroying ozone in the upper atmosphere.*

Each container should be labeled with the filler's name, address, and date filled. The cylinder should be labeled with a DOT green, 4 × 4-in, diamond-shaped nonflammable gas label (Figure 22-18). Each container should display a precautionary label prepared in accordance with ANSI Z129.1, American National Standard for Hazardous Industrial Chemicals—Precautionary Labeling. In addition, Federal Law 49, CFR Sections 172.301 and 172.302, must be followed. An example, the labeling that is standard on a DOT 39 disposable cylinder and its cardboard shipping carton, is shown in Figure 22-19. Federal law requires the label to include the following:

- Product identity
- Instruction in case of fire, spill, or leak
- Instruction in case of contact or exposure
- Signal word (such as DANGER!, WARNING!, or CAUTION!)
- Statement of hazards
- Instructions for container handling and storage
- Antidotes

TECH TIP

Refrigerants should never be mixed. This is why it is important to clearly mark the recovery cylinder to identify the type of refrigerant it contains. Only use the recovery cylinder for one type of refrigerant even if it has been emptied and then refilled again.

22.11 CYLINDER FILL LEVEL

The contents of any pressurized cylinder will increase in pressure if heated. As long as the cylinder still has some gas in it, the gas will compress and the rise in pressure will normally be slow enough that the built-in safety devices can relieve the pressure when it exceeds 150 percent of the cylinder service pressure. However, if the cylinder is filled completely with liquid, a relatively small rise in temperature can create a very quick rise in pressure. This is because liquid is not compressible. A cylinder that is filled with liquid can go from 100 psig to over 1,000 psig simply by warming up 10°F (Figure 22-20). This can cause a violent explosion. Neither the relief disk on disposable cylinders nor the relief valve on recovery cylinders can relieve pressure quickly enough if a cylinder full of liquid should rise in temperature by 10°F in a few minutes. This type of dramatic pressure increase due to liquid expansion is called hydrostatic pressure.

To prevent disaster, cylinders should never be filled more than 80 percent full of liquid by volume, and they should not be stored or used in temperatures exceeding 125°F. All refrigerant cylinders have a maximum recommended service pressure. This provides a good idea of how much pressure is too much. Do not pressurize recovery cylinders above their rated service pressure. More detail

on safely filling recovery cylinders is provided in Unit 28, Refrigerant Management.

CODES AND STANDARDS

ANSI/ASHRAE Standard 15-2010, Safety Standard for Refrigeration Systems, is directed toward the safety of persons on or near the premises where refrigeration facilities are located. The standard established safeguards for life, limb, health, and property and prescribes safety requirements.

22.12 ANSI/ASHRAE STANDARD 15-2010

ANSI/ASHRAE Standard 15-2010, Safety Standard for Refrigeration Systems, addresses the design, construction, operation, and testing of refrigeration systems. Mechanical considerations include the rupture or fracture of a component resulting in a release of refrigerant, fire, and explosion. Also addressed is the prevention of personal injury such as suffocation (asphyxiation), cardiac arrhythmia, toxic effects, corrosive attack, and freezing of tissue.

The potential risk of exposure depends on whether a refrigerant leak can enter an occupied space. These occupancy categories are listed in Table 22.4. Systems are classified as low probability or high probability within an occupancy area. The refrigeration system located in a high-probability area must be sized so that a complete discharge of its refrigerant does not exceed the concentration limits set by ANSI/ASHRAE Standard 34-2010. This does not apply to equipment containing less than 6.6 lb., certain laboratories, and industrial occupancies and refrigerated rooms as long as appropriate design conditions are met.

Table 22-4

Occupancy Classification	Examples
Institutional	Hospitals, nursing homes, asylums, prisons
Public assembly	Auditoriums, classrooms, passenger depots, restaurants, theaters
Residential	Dormitories, hotels, apartment buildings, private residences
Commercial	Offices, professional buildings, markets
Large mercantile	Shopping centers where more than 100 persons congregate
Industrial	Manufacturing where access by authorized persons is controlled
Mixed	Two or more occupancies located in the same building

Figure 22-21 Warning sign for a refrigeration machinery room.

Machinery Rooms

Refrigeration machinery rooms located indoors must follow special provisions. Access will be restricted to authorized personnel with clearly marked signs posted at the entrance (Figure 22-21). Doors will be tight fitting, open outward, be self-closing, and be sufficient in number to ensure freedom for persons to escape in an emergency. All machinery rooms are required to have detectors located in an area where refrigerant from a leak will concentrate.

The refrigerant detector will activate an audible and visible alarm and mechanical ventilation within the space at a value not greater than the corresponding TLV-TWA. The alarm must be manually reset, with the reset located inside the machinery room. Do not rely on an automatic detector to announce that the event is over. When entering the space, use a MSHA/NIOSH-approved SCBA if the refrigerant concentration levels are still excessive.

As a special case, ammonia systems require the mechanical ventilation system to be run continuously. Failure of the ventilation system will sound an alarm. Depending on local codes, there may be a provision for a manual emergency discharge of the ammonia refrigerant.

Machinery rooms that use refrigerants classified as flammable (A2, A3, B2, B3) must conform to Class 1, Division 2, of the National Electric Code. In addition, some machinery rooms are required to have a manual shutoff for the refrigeration equipment and a ventilation fan switch located immediately outside the machinery room door.

SAFETY TIP

The total amount of refrigerant stored in a machinery room in all containers not provided with relief valves and piping in accordance with ANSI/ASHRAE Standard 15-2010, Section 9.7, shall not exceed 330 lb.

Pressure Relief

Refrigeration systems need to have some method to relieve excessive pressure that can be caused by fire or other abnormal condition. A large refrigerant receiver contains mainly liquid refrigerant by weight. In the event of a fire, the excessive heat would cause the liquid refrigerant to turn into vapor. The refrigerant volume would greatly increase

Figure 22-22 Compressor internal pressure-relief valves.

while the receiver volume would remain the same. The resulting increase in hydrostatic pressure could rupture the receiver, causing a violent explosion.

Pressure-relief valves, rupture disks, and fusible plugs are installed to prevent this from happening. Pressure-relief valves may be set to relieve back to the low-pressure side of the system or through escape piping safely to atmosphere. Figure 22-22 shows two different internal relief valves found on refrigeration compressors that recirculate the discharge gas back into the suction side. They will reseal when the pressure returns to a safe level. External safety valves are sealed by the manufacturer and are marked with the data required by Section VIII, Division 1, of the ASME Boiler and Pressure Vessel Code.

Rupture disks are one-time failure devices that release the refrigerant upon excessive pressure. Rupture disks are marked with the data required in paragraph UG-129(e) of Section VIII, Division 1, of the ASME Boiler and Pressure Vessel Code. A rupture disk and its label are shown in Figure 22-23. Fusible plugs melt at a set temperature and will release the refrigerant as a one-time failure device. They are marked with the melting temperature in Fahrenheit or

Celsius. Both rupture disks and fusible plugs release directly into the atmosphere, so they are normally piped to direct the refrigerant safely outside the building in accordance with ANSI/ASHRAE Standard 15-2010, Section 9.

22.13 REFRIGERANT SENSORS FOR COMMERCIAL APPLICATIONS

ANSI/ASHRAE Standard 15-2010 requires that refrigeration machinery rooms be equipped with refrigerant sensors to sound a visible and audible alarm in the event of a release above the TLV-TWA. However, many building codes across the country are now being modified to meet new environmental regulations. This makes ANSI/ASHRAE Standard 15 increasingly open to interpretation by local jurisdictional codes. The standard is being applied for many different applications:

- Banana and produce rooms
- Beverage plants
- Bakeries
- Chemical plants
- Confined-space entry
- Food processing
- Gas bottling plants
- Ice rinks
- Product coolers
- Rack houses
- Refrigeration systems
- Supermarkets
- Wineries
- Mushroom farms
- Ice cream storage
- Poultry, meat, and fish processing

As an example, a typical walk-in cooler located in a supermarket can be interpreted as a “confined space,” creating the need for refrigerant-specific sensing. Ice rinks provide another example. Most ice rinks use R-22 as the refrigerant, but ammonia is becoming more popular in rinks because it does not bring the same environmental issues as halocarbon refrigerants. Refrigerant sensors may need to be placed strategically around the arena.

Figure 22-23 Rupture disk and label.

Sensor Types

There are many different sensor types. Some require pumps and filters to draw a sample of refrigerant into the sensor. These may take periodic samples rather than continuous samples. Other types, such as diffusion-type sensors, have no moving parts and will continuously monitor the space. Some sensors can detect more than one type of refrigerant, while others are designed for one refrigerant type only.

Ceramic metal oxide semiconductor (CMOS) sensors are the earliest versions. The conductivity of sensitized metal oxides will change when exposed to refrigerant gases. More common now are infrared sensors. The operation of this type is based on the principle that most gases absorb infrared energy (light) at a characteristic frequency (wavelength).

Infrared non-dispersive (NDIR) or absorptive infrared systems compare an air sample from the space to a sample of inert gas (usually nitrogen) stored in the monitor. The sample and the inert gas are irradiated with infrared light, and the light absorption of each is measured and compared. With this type of sensor, inaccuracies can occur over time and are referred to as “drift.”

Photoacoustic infrared (PIR) sensors eliminate the need to compare results to a reference sample and therefore reduce the possibility of drift. This type of sensor directly measures the changes in pressure that occur when an infrared light is absorbed by the refrigerant in the sample.

Diffusion-design sensors use infrared technology but do not require pumps or filters for sampling. This type of sensor utilizes a broadband infrared source to emit energy at the refrigerants narrow range of frequencies. The sensor contains a pulsed infrared source, a gas sample cell, an optical filter, and a detector. A released refrigerant gas collecting in the sample cell will absorb energy reaching the detector. This change in energy is detected, amplified, and sent to the signal-processing portion of the system. The space is monitored continuously, unlike a sample-draw system. This type of sensor can be used for most of the common refrigerants, including ammonia. The standard refrigerant detection range is 0–3,000 ppm, but units can be rescaled in the field if lower trip points are required. Ammonia can be detected over a range of 0 to 2 percent (20,000 ppm).

Electrochemical (EC) sensors can be used to detect concentrations in the low-ppm range and are often used for specific harmful gases such as carbon monoxide, chlorine and ozone. This type of sensor can also be desirable for toxic refrigerants such as ammonia. A pair of polarized electrodes is located within the sensor and isolated from the space by a gas-permeable membrane. When released ammonia passes through the membrane, a measured redox (oxidation reduction) reaction occurs, which is then amplified and sent to the signal-processing portion of the system.

Photoionization detectors (PIDs) can also be used for ammonia systems instead of EC sensors. Since EC sensors detect low ppm levels, they may not have the range required for determining high levels of concentration. Ammonia has an ionization potential of 10.18eV and can be readily measured with a PID containing a standard 10.6eV lamp. PIDs may have a range of up to 10,000 ppm, which is helpful when making appropriate PPE decisions.

SAFETY TIP

These are the recommended personal protection guidelines for an ammonia release:

- Over 35 ppm for 15 minutes: put on a respirator.
- Over 250 to 300 ppm: put on a SCBA.
- Over 250 to 5,000 ppm: put on Level A suit.
- Over the LEL (lower explosion limit): evacuate the area.

Sensor Location and Maintenance

A single sensor takes a sample at the location where it is mounted. Some sensors are equipped with multipoint sampling that allows samples to be taken at more than one location by a single sensor. A good rule of thumb is that there should be a sensor or sample point between each chiller located in a machinery space. As an example, for two chillers, sample between them; for three chillers, sample between each pair of chillers; etc. For refrigerated product storage areas (cold rooms), a sensor should be installed for each 20,000–30,000 cu ft of room volume. As an example, a banana storage room that is 20 ft high, 40 ft long, and 35 ft wide would take up 28,000 cu ft of space.

TECH TIP

1 lb of refrigerant will evaporate to occupy about 3 to 4 cu ft of volume. To put this in perspective, consider that a basketball takes up about 1 cu ft of space, so about 3 to 4 basketballs. This 1 lb of refrigerant would spread out if released into a 30,000–40,000 cu ft space. The average concentration resulting from 1 lb of refrigerant released into the space would be about 100 ppm.

The sensor should be located where the leak is most likely to occur. CFC/HCFC/HFC vapors are heavier than air and will settle to a low area. In this case, sensors should be mounted about 1–2 ft from the floor, close to the potential leak source. Because ammonia is lighter than air, this type of sensor would be mounted near the ceiling. If the primary application for the sensor is for personal protection (TLV-TWA) then mount the sensor at a height in the breathing zone of the employees, typically 5 ft off the floor.

Airflow patterns in the space must be taken into account so that the sensor is mounted downstream from the potential leak source. Place it in a location that is easily accessible for calibration and maintenance. Do not mount the sensor over a door. Sensors may also be located in refrigerant safety vent lines to protect against and accidental loss of refrigerant due to a slowly leaking relief valve, rupture disk, or fusible plug.

The sensor should not be placed in locations of excessive humidity or in a water wash-down area unless the sensor is specifically designed for such use. A sensor utilizing a

sample-draw system could have ice form in the draw tube, which would block the lines and disable the system. There are some sensors that are specifically built to resist dust and water for mounting in harsh locations. They can operate in conditions of 100 percent relative humidity and at ambient temperatures as low as -40 to -50°F .

For routine maintenance, sensors should be exposed to a refrigerant sample on a monthly basis to ensure that they are operating correctly. This will also provide a check for the visible and audible alarms. Infrared sensors should have signal voltages measured and logged on a regular basis. Calibration should be performed with certified calibration gas every six months. Calibration kits to perform these tests can be obtained from the equipment manufacturers. All tests and calibrations should be logged.

UNIT 22—SUMMARY

Safety in the workplace is always the number-one priority. The hazards that can result from refrigerant exposure and misuse fall into a number of different categories: toxicity, frostbite, flammability, explosion, decomposition, and pressure. Varying levels of toxicity can result from short-term exposure to high concentrations or long-term exposure to lower concentrations. Acceptable levels are referred to as threshold limit values (TLV). Frostbite results from direct exposure and can be avoided by wearing the correct PPE. An explosion could result from a flammable refrigerant, which is different as compared to a cylinder rupturing because of excessive pressure. Both cases can lead to serious injury or even death. Always refer to the refrigerant MSDS, because even some nontoxic refrigerants can produce poisonous gases if exposed to a flame. To protect yourself and the customer, always take proper precautions, wear the appropriate PPE, and review the refrigerant MSDS before servicing any refrigeration system.

Refrigerant System Servicing and Testing Equipment

OBJECTIVES

After completing this unit, you will be able to:

1. list the different types of thermometers.
2. explain the advantages and disadvantages of each type of thermometer.
3. list common air temperature measurements technicians make.
4. list the different types of gauges that can be used to measure pressure.
5. explain how gauge accuracy is stated.
6. explain the operation and use of a manifold gauge set.
7. list the types of positive-shutoff low-loss fittings available.
8. explain why a micron vacuum gauge is used to measure vacuum instead of a compound gauge.
9. list the different types of refrigerant leak detectors.

23.1 INTRODUCTION

Measuring and testing is the only way an HVACR technician can verify correct system installation and operation. Technicians engaged in installing, servicing, and troubleshooting HVACR systems need to measure the performance of the refrigeration system. During installation, technicians measure the vacuum level using vacuum gauges. System pressures and temperatures are measured to verify system operation. The temperatures and pressures within a refrigeration system are key pieces of information that all HVACR service technicians need to diagnose refrigeration problems. Instruments that test temperature, pressure, and vacuum and check for refrigerant leaks are all essential to HVACR work. Testing and measuring to verify correct operation is the only way to ensure that high-efficiency equipment will perform as designed.

Most of the instruments used are digital, although many analog instruments are still in use. The introduction of digital electronics to temperature and pressure sensing has greatly increased both accuracy and speed. Today's test instruments can provide readings to one or more decimal points. That level of accuracy is often important to ensure that the system is not only running but also operating at the highest efficiency.

TECH TIP

Sometimes people confuse thermometers and thermostats. The difference between a thermometer and a thermostat is that a thermometer simply indicates the temperature. A thermostat controls equipment based on the temperature it reads.

23.2 TEMPERATURE MEASUREMENT

HVACR technicians measure temperature daily, and taking accurate temperature readings is an essential part of the job. System performance is affected by the temperature of the air or water flowing through the units. System performance affects the temperature of the final product. Temperature readings allow technicians to monitor system operating conditions and system performance. The performance of particular refrigeration system components can often be determined by taking temperature readings. Part of taking accurate temperature readings is using the right thermometer. There are many types of thermometers available, including glass stem, dial, digital, and infrared. Each type has advantages and disadvantages. Some types of thermometers are better suited for a particular job than others are.

23.3 GLASS-STEM THERMOMETERS

Glass-stem thermometers once were commonly used by refrigeration service people. The temperature is measured on a scale by comparing the tip of the liquid inside the thin tube to a scale on the side of the tube. Any liquid can be used, but mercury and alcohol are the most commonly used. Mercury looks metallic in color, and alcohol is usually dyed red (Figure 23-1). The thinner the size of the hollow glass tube, the greater the movement per degree of temperature change. Glass thermometers are available from pocket-sized models to longer, more accurate models for laboratory work. Breakage is a problem since glass thermometers are fragile. Many technicians would consider the slow response time of this type of thermometer to be a disadvantage.

An advantage of the glass-stem thermometer is that they are highly reliable. They do not rely on any mechanical

Figure 23-1 Glass-stem thermometer.

Figure 23-2 Glass-stem thermometers: (a) in protective case; (b) with glass tube exposed.

or electronic device that might stick or quit working (Figure 23-2). Their reliability and relative low price are reasons they are extensively used on large central-heating and cooling plants used in large buildings or factories.

23.4 DIAL THERMOMETERS

Dial thermometers indicate temperature by a pointer moving over a circular scale (Figure 23-3). The pointer moves because it is attached to a piece of metal inside the thermometer that

Figure 23-3 Dial-type pocket thermometer.

has a high rate of thermal expansion and contraction with temperature changes. The metal inside the thermometer can be straight or it may be wound into a spiral or spring. If it is straight, it expands linearly; if it is in a spiral or spring, it rotates (Figure 23-4). Spiral or spring-wound metal strips are constructed from two different types of metal attached together. Because each strip of metal has a different rate of thermal expansion, the twisting or bending motion is greater than it would be if a single type of metal were used. An advantage of dial thermometers is that they are more rugged than glass-stem thermometers and can be used for a wide variety of applications. A disadvantage is that they are not as accurate as either glass-stem thermometers or digital thermometers.

23.5 DIGITAL THERMOMETERS

Digital thermometers with compact sensing elements are popular because of their speed in sensing a change in temperature and the ease in reading the alphanumeric display instead of a dial or a scale (Figure 23-5). Most digital thermometers require batteries or a source of electrical power to produce the digital display. The display can be easily changed to display the temperature reading in the Fahrenheit or Celsius scales.

Advantages of digital thermometers are the many features available on some models, including temperature differences between two or more sensing elements, highest and lowest temperatures, average temperature, and lighted displays. They are useful in measuring surface temperatures, such as suction superheat temperatures when adjusting an expansion valve.

Figure 23-4 Spiral or spring-wound dial thermometer operation.

23.6 THERMOCOUPLE TEMPERATURE SENSORS

Thermocouple temperature sensors can be used to detect temperatures that are displayed on analog or digital instruments. The thermocouple produces a small voltage when two dissimilar metal wires are joined, forming a tip or junction that can be heated or cooled. A number of dissimilar metals, such as chromel and alumel or iron and

constantan, are used in commercially available thermocouple wires. Type J (iron and constantan) sensors have been used for years but are being replaced with the more popular type K (chromel and alumel) because of its lower cost. One problem with thermocouple sensors is their accuracy. They may provide a temperature that is 2°F higher or lower than the actual temperature. You can test the accuracy of a thermocouple by comparing its temperature reading with another type of thermometer. Once you know the temperature error factor, you can mark it on the thermocouple. That way, you can add or subtract a degree or two as needed to keep the error factor within an acceptable range for most HVACR work.

Some of the advantages of thermocouples are their relative low cost, which makes them readily available, and their flexibility. They can be attached to several locations inside the equipment, and the equipment cover panels can then be reinstalled. With the thermocouple leads run so they are outside the cabinet, the equipment can be operated normally. Now the technician can better diagnose what is happening to temperatures inside the operating equipment.

When taking the temperature of a refrigerant line, make sure the tip of the thermocouple is tightly pressed against the line. You should also insulate the tip, because thermocouples are very sensitive to their surrounding temperature. Some meter manufacturers supply a short strip of Velcro to wrap around the thermocouple tip to hold the tip securely against the refrigerant line and insulate it.

To make it easier to get accurate refrigerant line temperatures, some manufacturers produce line-clamping thermocouple heads (Figure 23-6). These clamping thermocouples provide both a tight connection and insulation from ambient air, Figure 23-7.

Figure 23-7 Line-clamping thermocouple head. (Courtesy of HVAC Department Terra Community College, Freemont, Ohio)

TECH TIP

Sometimes the thermocouple leads used with digital temperature gauges may have a slight error in the temperature reading. For this reason, it is a good idea to test a new set of temperature probes against each other or against another temperature-measuring instrument. This comparison will allow you to determine the accuracy and any variance in readings that you may receive from these leads. If you consistently find a variance greater than 1° between any lead and other test instruments, mark that lead with the amount of temperature difference required to make the reading accurate. This will allow you to make corrections in temperature readings when using this probe.

A digital thermometer can be used with a wide variety of probes, three of which are shown in Figure 23-8. The different probes allow the single thermometer to be used for more applications.

23.7 INFRARED THERMOMETERS

An infrared thermometer can “see” the temperature of a surface from a distance. What it is seeing is the color of the invisible infrared (IR) light given off by the object. A detector is located inside the instrument that senses the infrared light waves. A change in the IR light’s color occurs as a result of temperature changes, which results in a change in the electrical output of the detector. A small integrated circuit converts that electrical output into a displayed temperature.

Figure 23-8 Temperature sensor probes: (a) temperature sensor for refrigerant piping; (b) ambient temperature sensor with clamp; (c) flame-sensing temperature probe.

The distance the detector is from the object, the surface color, and its reflectance or reflectivity all affect the accuracy of the temperature read. The most accurate reading obtained is when the detector is closest to a black, dull surface. However, not all HVACR field work requires extreme accuracy. Technicians are often looking for trends in temperature change. For example, a technician may need to determine if the air coming from a duct is colder or warmer than it was before the system adjustment was made (Figure 23-9).

SERVICE TIP

A disadvantage of IR thermometers is that they cannot detect air temperatures; however, they can detect the temperature of the grille or register that the air is passing through. To obtain the most accurate estimate of the actual duct air temperature, point the detector into the louvers so it is pointed at the inside of the duct boot. Some IR thermometers have a laser pointer to make this easier. Move the instrument around and watch the temperature display. Watch for the highest or lowest temperature (highest for heating and lowest for AC) indicated on the display. That temperature is going to be the closest to the actual air temperature. Practice will help develop your skill in obtaining accurate temperature readings with an IR thermometer.

Figure 23-9 Using an infrared thermometer for measuring air damper temperature.

There are many advantages of infrared thermometers. The fact that a temperature reading can be made from a distance may mean that you do not need to climb a ladder to get air duct readings. It may also mean that you can get a reading from the back of a hard-to-reach space. The temperature is displayed instantaneously, which speeds up your work.

23.8 TAKING ACCURATE TEMPERATURE READINGS

Getting accurate temperature readings requires the right equipment and the right techniques. Common temperatures read while working on HVACR equipment include air, water, and refrigerant line temperatures.

Air temperature can be read with dial-type pocket thermometers, digital pocket thermometers, or electronic temperature testers. Infrared thermometers are less desirable for air temperature readings, because they must read the temperature of objects. However, an infrared thermometer can be used to measure air by targeting the register where the air is leaving.

Water temperature readings can also be read with dial-type pocket thermometers, digital pocket thermometers, or electronic temperature testers. If possible, the thermometer should be inserted directly into the water stream. When using electronic thermometers, be sure that the sensor is rated for liquid immersion. Infrared thermometers do not work well for measuring liquid. An infrared thermometer can be used if the water is contacting an object that the infrared can target.

Pipe temperatures are best taken with a thermocouple temperature tester. Probes are available with clamps that hold the thermocouple against the pipe (Figure 23-10). Bead-type thermocouples can be held against the pipe with a Velcro strap for an accurate reading. Pocket-type thermometers can be used only if the tip can be held securely against the pipe and insulated from the surrounding air. A Velcro strap or Permagum can be used to hold the tip of the thermometer against the pipe and insulate it from the surrounding air. Most infrared thermometers are not suited for measuring pipe temperature because of their distance to

Figure 23-10 Thermocouple clamp on pipe.

Figure 23-11 Thermometer well with stem thermometer in it. (Courtesy of Ritchie Engineering Company, Inc.-Yellow Jacket Products Division)

spot ratio. Infrared thermometers with a spot ratio of 10:1 or greater will work fine with dull pipes larger than $\frac{1}{2}$ in. The emissivity of the pipe can also be a problem for shiny materials like copper.

Some systems are equipped with thermometer wells. These are designed for use with thermometers that have metal stems, like pocket thermometers (Figure 23-11). The well should be filled with mineral oil to ensure good thermal contact between the well and the thermometer.

23.9 AIR TEMPERATURE READINGS

Three air temperatures are commonly read when working on air-conditioning equipment: the outdoor ambient temperature, the return air temperature, and the supply air temperature. Ambient temperature is the temperature around the unit, typically outside. Return air is the air returning to the system from the conditioned space. Supply air is the conditioned air being supplied to the conditioned space.

Outdoor Ambient Temperature Readings

Outdoor ambient temperature readings should be taken in areas that are free from discharge air from condensing units or dryer vents and out of direct sunlight. Holding the thermometer in front of the air intake grille of the outdoor unit normally works well.

Return-Air Temperature

Accurate return-air temperatures can be obtained by holding a pocket or digital thermometer in front of the return air grille. Infrared thermometers can be used with return-air grilles by targeting the grille.

Supply-Air Temperature

Supply-air temperatures can be more difficult. The unit should operate long enough for supply-air temperatures to

Figure 23-12 Thermometer reading supply-air temperature.

stabilize. If possible, the thermometer should be inserted inside the supply-air register (Figure 23-12). When the supply air leaves the register, it mixes with room air, affecting the temperature of the supply air. Infrared thermometers can be used with supply-air registers by targeting the supply-air register. When measuring supply-air temperature with an infrared thermometer, the unit must run long enough for the register to be the same temperature as the supply air.

Duct Temperatures

The temperatures read at the registers will be different from the temperature at the unit because of duct loss and gain. When checking a system performance specification, such as furnace temperature rise, it is best to check temperatures at the unit. Drilling a small hole in the ductwork allows temperature readings of the air just as it enters and leaves the unit. Holes should generally not be drilled in the actual unit or in flex duct. A hole in the wrong place in the unit can damage the unit. Flex ducts should not be pierced; poking holes in a flex duct allows air to pass between the inner and outer jacket. This increases duct loss and can lead to condensation on and inside the duct.

The return-air plenum is the best location for checking return-air temperatures, especially if there are several return ducts. The thermometer will read the mixed air temperature, which may be different from the temperature in individual returns. If there are any components installed in or on the plenum, be careful to avoid them. The temperature of air flowing to the return air through a bypass humidifier or bypass damper will be a very different temperature than the rest of the return air.

The supply-air plenum can be used on systems with a radial duct design using flex duct. The hole in the plenum should not be too close to where the plenum connects to the unit. When possible, take supply-air temperatures in a trunk duct leaving the plenum (Figure 23-13). This avoids the problems of radiant heat from furnace heat exchangers or interference from components installed inside the plenum.

Figure 23-13 Thermometer placed in hole in supply duct.

SAFETY TIP

When drilling holes in ductwork to measure temperature, make certain you know what is on the other side of the duct; hopefully just air. Contacting a set of electric heat strips with a metal thermometer that is sticking through a metal duct can cause a direct short on a high-current device and give you a serious shock!

23.10 PRESSURE MEASUREMENT

The proper operation of refrigeration equipment depends upon maintaining the correct pressures throughout the system. HVACR technicians must be able to check system operating pressures to verify correct operation. Pressure readings are often necessary when diagnosing system problems. The first step in obtaining accurate pressure readings is having equipment that matches the job. Gauges must be designed to work with the particular refrigerant and pressures being measured. Technicians must be familiar with the range of pressures that can be expected inside the equipment. They must also know what equipment is required for those pressure measurements. Using the wrong tool can not only lead to incorrect readings, but it can also be dangerous.

CAUTION

Do not use any refrigerant gauge sets on R-410a that are not rated for its higher pressures. It is dangerous to use older gauge sets designed for R-22 because they can be damaged by the higher R-410a system pressures.

23.11 REFRIGERATION GAUGES

Mechanical gauges require a physical device to translate pressure changes into movement that can be used to move a dial. Three types of devices are used in mechanical gauges: diaphragm, bellows, and Bourdon tube. Diaphragm gauges are generally used for lower pressures within a limited range and are usually not used in refrigeration. Bellows gauges are used in refrigeration gauges, but they are not as common as Bourdon tube gauges. The bellows expand with an increase in pressure and contract with a decrease in pressure. Figure 23-14 shows a bellows gauge used in refrigeration.

Most refrigeration gauges use a Bourdon tube as the operating element. The Bourdon tube is a flattened metal tube that is sealed at one end, curved, and soldered to the gauge fitting at the other end (Figure 23-15). Figure 23-16 illustrates how a Bourdon tube operates. The blue shaded section shows the tube at rest at atmospheric pressure. A rise in pressure inside the tube tends to make the Bourdon tube mechanism straighten. The position the Bourdon tube will move to when pressure is applied is shown in Figure 23-16 in the dotted outline. This movement will pull on the link, which will turn the gear sector counterclockwise. The pointer shaft will move clockwise to move the needle. On a decrease in pressure, the Bourdon tube moves clockwise toward its original position and the pointer moves counterclockwise to indicate a decrease in pressure.

Pressure Gauges

The high-pressure gauge has a single continuous scale. Gauge sets made for refrigerants such as R-134a and R-22

Figure 23-16 The dashed line shows how the Bourdon tube responds to a pressure increase.

are usually calibrated (marked off) to read 0 to 500 psi. Figure 23-17 shows a high-pressure gauge. The scale is usually marked in 5-lb increments. On most gauges, the outer scale is the pressure scale and the inner scales indicate the saturation temperature of different refrigerants at the indicated pressure. For example, if the gauge pointer indicated 200 psi pressure for R-22, the saturation temperature of the refrigerant would be approximately 101°F.

Figure 23-19 Compound gauge for most common refrigerants, except R-410a. (Courtesy of Ritchie Engineering Company, Inc., Yellow Jacket Products Division)

Figure 23-18 High-side pressure gauge for R-410a. (Courtesy of Ritchie Engineering Company, Inc., Yellow Jacket Products Division)

Pressure gauges made for R-410a have a higher pressure range because of the higher pressures of R-410 systems. R-410a pressure gauges can typically read pressures up to 800 psig. On an R-410a pressure gauge, each mark on the pressure scale represents 10 psig pressure. Figure 23-18 shows a high-pressure gauge for R-410a systems.

Compound Gauges

The low-side gauge is a compound gauge that measures both pressure and vacuum (Figure 23-19). Gauge sets made for refrigerants such as R-134a and R-22 are usually calibrated from 0 to 30 in of mercury vacuum and from 0 to 120 psig pressure. On a typical compound gauge, each mark on the vacuum scale represents 2 in Hg vacuum, and each mark on the pressure scale represents 1 psig pressure.

It is common for the standing pressure on the low side of a system to exceed the normal range of the compound gauge. The retard range protects the gauges from damage when a pressure above their normal range of operation is connected to them. Gauges for R-134a and R-22 typically have a retard range of up to 350 psig.

Compound gauges made for R-410a have a higher pressure range because of the higher operating pressures of R-410a systems. R-410a gauges can typically read pressures up to 350 psig and have a retard range up to 500 psig. On an R-410a compound gauge, each mark on the pressure scale represents 5 psig pressure. Each mark on the vacuum scale represents 5 in Hg vacuum. On the gauge shown in Figure 23-20, each mark on the vacuum scale represents 10 in Hg vacuum.

Figure 23-21 Comparison of 2½-in, 3⅛-in, and 4-in mechanical gauges. (Courtesy of Ritchie Engineering Company, Inc., Yellow Jacket Products Division)

Like the high-pressure gauge, the compound gauge also has scales calibrated to read saturation temperatures of various refrigerants, such as R-134a, R-22, and R-410a. With these scales, it is not necessary to refer to pressure-temperature tables or curves to calculate pressure-temperature relationships. Figure 23-20 shows a compound gauge for an R-410a system.

Gauge Accuracy

Gauges are classified by their percentage accuracy. Class 1 gauges are accurate to $\pm 1\%$ of the reading throughout their range. This means that 100 psig can read anywhere between 99 and 101. Class 1 gauges are the most accurate mechanical gauges used in refrigeration. Class 1.6 and class 2 gauges are accurate to 1.6 percent and 2 percent, respectively. Class 2-3-2 gauges are accurate to 2 percent for the first third of their scale, 3 percent for the middle third, and 2 percent for the final third of their scale. Class 3-2-3 gauges are accurate to 3 percent for the first third of their scale, 2 percent for the middle third, and 3 percent for the final third of their scale.

Gauge Size

Gauges are available in different sizes. The most common sizes are 2½-in, 3⅛-in, and 4-in diameter. Figure 23-21 shows all three common sizes of gauges. Larger gauges are easier to read than smaller gauges. Their larger circumference produces increments that are spaced further apart, making them easier to read and more accurate. This is especially important for gauges that are used over a wider range of pressures (e.g., gauges designed for use with R-410a).

Liquid-Filled Gauges

During operation of an AC or refrigeration system, the high-side pressure may rapidly pulsate as the compressor

Figure 23-22 High-pressure needle vibrating due to compressor pulsing.

valves open and close. This pulsation can cause the high-side gauge needle to flutter or vibrate (Figure 23-22). Liquid-filled analog gauges are available that reduce needle flutter. They contain glycerin to dampen pulsations, lengthen service life, and improve accuracy (Figure 23-23).

Digital Gauges

The most advanced gauges use digital pressure transducers to read pressure instead of the Bourdon tube gauges (Figure 23-24). They reduce reading error by displaying the pressure directly in numbers. Digital gauges can show pressure changes in increments down to 1/10 lb while analog gauges do well to show changes smaller than 5 psig. Digital gauges

Figure 23-23 Liquid-filled gauges dampen needle vibration.

Figure 23-24 Digital manifold gauge set. (Courtesy of Ritchie Engineering Company Inc.-Yellow Jacket Products Division)

also provide accurate built-in saturation temperature correlation for several refrigerants. The digital gauge shown in Figure 23-24 can simultaneously display many important system operating characteristics, including the following:

- Evaporator pressure
- Evaporator saturation temperature

- Suction-line temperature
- Suction-line superheat
- Condenser pressure
- Condenser saturation temperature
- Liquid-line temperature
- Liquid-line subcooling

SERVICE TIP

Refrigeration gauges have a small adjustment screw that allows the gauge to be zeroed. The gauge is adjusted to zero with the hoses open to atmospheric pressure. However, it is possible for a gauge to zero out but not read other pressures accurately. From time to time, the technician should attach the gauges to a new cylinder of refrigerant at a known temperature and compare the pressure reading to the temperature-pressure chart so that the gauge can be checked for accuracy. Gauges that are zeroed and are still inaccurate should be replaced.

23.12 READING REFRIGERANT SATURATION TEMPERATURES

Refrigeration gauges not only read system pressure but also show the refrigerant saturation temperature of common refrigerants. The saturation temperature of a refrigerant may be determined by observing the colored scale for that particular refrigerant. The gauge in Figure 23-25 is showing 150 psig for an R-410a system. The needle also points toward its corresponding saturation temperature, 53°F. The high-pressure gauge shown in Figure 23-26 indicates a pressure of 365 psig and a corresponding temperature for R-410a of 110°F.

Figure 23-25 This gauge is reading 150 psig with a saturation temperature of 53°F for R-410a.

Figure 23-26 This gauge is reading 365 psig with a saturation temperature of 110°F for R-410a.

Digital gauges often have built-in saturation temperature tables for multiple refrigerants. The refrigerant saturation temperature is displayed by pressing a button on the gauge. The saturation temperature display of digital gauges is considerably more accurate than on analog gauges. They can also hold data for many types of refrigerant, compared to the two or three types that analog gauges can display.

23.13 GAUGE MANIFOLD SET

Technicians use the gauge manifold to diagnose trouble in refrigeration systems. Gauges allow the operator to watch both gauges simultaneously during evacuation or charging operations and save time on almost any work that must be done on the system. The most common gauge manifold test sets contains two shut-off valves, three external connections, and two pressure gauges, Figure 23-27. Manifolds are also available with extra ports, valves, and hoses. The gauges and the flexible hoses that connect to the manifold to connect it to the system are color coded; blue is the low side of the system, while red is the high side. The left-hand gauge is called a compound or suction pressure gauge. The blue hose connects to the low side of the system, allowing the blue compound gauge to read the system low-side pressure. The red hose connects to the high side of the system, allowing the red high-pressure gauge to read the system high-side pressure. The center yellow hose is useful for connecting to the charging refrigerant cylinder, vacuum pump, or recovery machine. Figure 23-28 shows a gauge set with color-coded gauges and hoses. Standard hoses have 1/4-in inside diameter and are designed to seal on a 1/4-in male flare end. Typically, one end is straight and connects to the manifold and the other end is angled to allow easier connection to service valves.

Figure 23-29 Four-valve manifold gauge set. (Courtesy Stride Tool)

Four-Port Manifolds

More advanced gauge manifolds are available that have four hose connections and four shutoff valves (Figure 23-29). Besides the low-side and high-side connections, there are two center connections, each with its own shutoff valve. Typically, one of the middle connections allows the use of a $\frac{3}{8}$ -in hose for faster evacuation. The extra shutoff valves give the technician more control over the flow through the manifold.

Large-Bore Manifolds

The hole through the middle of the manifold is called the bore. Standard-gauge manifolds have a bore of $\frac{1}{4}$ in, the same as the typical hoses used on standard gauge manifolds. The $\frac{1}{4}$ -in bore becomes a bottleneck and slows down evacuation and recovery through the gauge set. Manifolds are available with a larger $\frac{3}{8}$ -in bore (Figure 23-30) and $\frac{1}{2}$ -in bore (Figure 23-31). The $\frac{1}{2}$ -in bore manifold set uses

Figure 23-30 Manifold with $\frac{3}{8}$ -in bore. (Courtesy of Ritchie Engineering Company, Inc., Yellow Jacket Products Division)

Figure 23-31 The Megaflow manifold has a $\frac{1}{2}$ -in bore and several hose connections.

$\frac{3}{8}$ -in and $\frac{1}{2}$ -in hoses with $\frac{1}{4}$ -in connectors on the end that connects to the unit. The difference in evacuation speed between the $\frac{1}{2}$ -in bore manifold and standard $\frac{1}{4}$ -in bore manifolds is dramatic.

SAFETY TIP

There are two major groupings of gauge manifold sets. One group is designed to be used with R-12, R-22, R-134a, R-408A, R-407C, and R-404A. The other groups of gauge manifold sets are designed to be used with R-410A only. Do not use gauges designed for the lower-pressure refrigerants on the very-high-pressure R-410A system.

23.14 REFRIGERATION HOSES

The refrigeration hoses are an important part of a gauge manifold set. They are what actually connects the gauges to the system. Charging and vacuum hoses are available in sizes of $\frac{1}{4}$ in, $\frac{3}{8}$ in, $\frac{1}{2}$ in, and $\frac{5}{8}$ in inside diameter. The most common size is $\frac{1}{4}$ in. Refrigeration hoses are available in many colors (Figure 23-32). Many gauge sets use hoses that are color coded to the gauges: red for the high side, blue for the low side, and yellow for the center hose. Many four-port gauge manifolds have a $\frac{3}{8}$ -in port for vacuum and come equipped with a $\frac{3}{8}$ -in hose. Typical charging hoses have a straight end that connects to the manifold and an angled end that connects to the system. The angled end contains the core depressor for Schrader valves (Figure 23-33).

Figure 23-32 Refrigeration hoses are available in many colors. (Courtesy of Ritchie Engineering Company, Inc., Yellow Jacket Products Division)

Figure 23-33 The angled end contains a core depressor for Schrader valves.

TECH TIP

Manifold gauge sets have $\frac{1}{4}$ -in male flare connectors for attaching the system end of the hoses when the hoses are not in use. These fittings are there to keep dirt out of the hose end. Any dirt that gets into the hose end will be pushed into the next system you access. It is important to keep the hose ends clean by keeping them on these connectors when not in use.

Refrigeration hoses are not simply a single tube; they are built in layers. Figure 23-34 illustrates the construction of a refrigeration hose. The rubber seen on the outside simply provides physical protection for the inner layers. The woven fabric layer just under the outer rubber layer provides

**Inner rubber tube

Figure 23-34 Diagram of refrigeration hose construction.

strength. Some refrigeration hoses have two more inner layers, while others have only a single inner layer. The innermost layer actually contains the refrigerant. Hoses with two inner layers have extra permeation protection.

Hoses designed for use with refrigerants that operate at pressures lower than R-410a typically have a working pressure of 500 psig and a minimum burst pressure of 2,500 psig. Hoses designed for use with R-410a typically have a working pressure of 800 psig and a minimum burst pressure of 4,000 psig.

TECH TIP

The small O-ring in the end of the service valve hose is a replaceable part. These O-rings will become damaged over time and will need to be replaced to prevent refrigerant and vacuum leaks from occurring at the service valve connections. It is a good idea to carry a small package of these replacement seals with your tools because from time to time the O-rings will need to be replaced and occasionally one may fall out. When the O-ring falls out of the hose end, the hose cannot be used until a new O-ring has been installed.

23.15 POSITIVE SHUTOFF FITTINGS

Whenever gauges are connected to a charged system, the hoses are filled with refrigerant. With standard hose ends, the refrigerant in the hoses comes out of them when they are disconnected. Positive shutoff fittings allow technicians to control the flow of refrigerant leaving the hoses. They may be built into the hose, or they may be part of an adapter that connects to a standard hose. Positive shutoff fittings reduce refrigerant loss when connecting and disconnecting refrigeration hoses. They also protect the technician by reducing the amount of refrigerant spray that occurs when disconnecting refrigerant hoses. Positive shutoff fittings are very helpful when connecting and disconnecting to the high side of the refrigeration system, particularly on the liquid line. They are less important for the low side. Positive shutoff fittings are actually an annoyance for the middle hose because they create a restriction to flow and will not allow refrigerant purging out of the end of the middle hose. Some types of positive shutoff fittings include check valves built into the end of the refrigeration hose (Figure 23-35), check valve adapters, and short hoses with a ball valve (Figure 23-36).

TECH TIP

Consider the purchase of “low-loss” fittings when purchasing a manifold set.

Figure 23-35 A standard hose end, shown on top, compared to a check valve hose end, shown on bottom.

Figure 23-36 Refrigerant hose extensions with mechanical shutoff valve.

23.16 GAUGE MANIFOLD OPERATION

It is important to understand how the valves on a gauge manifold operate. Figure 23-37a shows a diagram of a standard set of manifold gauges. The valves do not control the flow of refrigerant to the gauges. Instead, they control the flow of refrigerant to the center port. The low-side gauge will always read pressure whenever the blue hose is connected to pressure. The high-side gauge will always read pressure whenever the red hose is connected to pressure. It is not necessary to open the hand wheels to read pressure. In fact, opening both valves will cause the two pressures to equalize through the manifold, making the readings inaccurate.

The hand wheels that control the valves on the end of the manifold can be set in one of three positions: fully closed, fully open, or partially opened. When both hand wheels are closed and the hoses are connected to the system, the low-side gauge will indicate the system low-side pressure and the high side will indicate the system high-side pressure (Figure 23-37b).

When the low-side hand wheel is turned open slightly, a partially open path around the valve and valve seat is

opened from the low side to the center hose (Figure 23-37c). This is the way a system can be charged with refrigerant. The slight opening allows the technician to control the flow of refrigerant into the system. As the valve is fully opened, free flow between the low side and the center hose can occur (Figure 23-37d). This is the position that would be used to recover only vapor refrigerant from the low side of the system.

When the high-side hand wheel is turned open slightly, a partially open path around the valve and valve seat is opened from the high side to the center hose (Figure 23-37e). This is how the valve is operated when a little liquid refrigerant is being removed from the system. The slight opening allows the technician to control the flow of refrigerant out of the system. As the valve is fully opened, free flow between the high side and the center hose can occur (Figure 23-37f). This is the position that would be used to recover liquid refrigerant from the high side of the system.

When both hand wheels are fully opened, a free-flowing path between the low side, high side, and center port is provided (Figure 23-37g). This is the position for the valves when a vacuum is being pulled on the system or when the entire refrigerant charge is being recovered.

Gauge manifolds designed especially for evacuating and dehydrating a system have larger hose connections and use larger-diameter hoses (Figure 23-38). The larger, usually $\frac{3}{8}$ -in. inside diameter of the hoses and valves reduces the pressure drop that occurs when pulling a vacuum. Reducing even the very small pressure drop that occurs in normal gauge manifolds can cut the evacuation time by up to 90 percent.

Some gauge manifolds have multiple openings on the utility connection to accommodate various devices being used simultaneously. The additional connections allow you to change from evacuation to charging without losing any of the system vacuum or refrigerant.

SERVICE TIP

The needle on the high side will sometimes start to flutter, making it hard to read. Normally, it does not flutter when the gauges are first attached. That is because the needle flutters when the high-side hose and valve get full of liquid refrigerant. Liquid refrigerant is drawn to the cooler hose as vapor condenses in the manifold and hose. Liquids are noncompressible, so the pulsing pressure in the high-side line is transmitted directly to the gauge when the hose fills with liquid (Figure 23-39a). First, close the cylinder valve so none of the system refrigerant charge will be lost. Now slightly open the high-side valve to let the liquid flow into the center hose (Figure 23-39b). This will dampen the needle fluttering for a moment, allowing you to get a pressure reading. After you have the pressure reading, close the high-side valve. Next, slightly open the low-side valve to let the liquid refrigerant that collected in the hose be drawn back into the system through the low-side service valve (Figure 23-39c). By putting the refrigerant back into the system, the refrigerant charge is not changed.

23.16 DIGITAL SYSTEM ANALYZERS

There are a number of combination temperature and pressure test instruments available for HVACR service work. These combination instruments are most often used to compare the system's high- or low-side pressure to the actual refrigerant line temperature. This is done to determine the system's subcooling (high side) or superheat (low side). Subcooling and/or superheat measurements are used to determine how a system is operating. Subcooling and superheat measurements are also used to determine if the system's refrigerant charge is correct or needs to be adjusted.

Subcooling and superheat meters have a pressure port that is attached to the refrigerant's access valve

Figure 23-39 Illustration of service tip: (a) high-side gauge needle vibrating due to liquid flooding; (b) gauge needle dampened as liquid is slowly bled into center hose; (c) bleeding liquid from center hose back into system.

and a thermocouple that is attached to the refrigerant line (Figure 23-40). For checking the subcooling, both the pressure port and thermocouple are attached to the high side. To check the superheat, both the pressure port and thermocouple are attached to the low side. The meter calculates and displays the subcooling or superheat reading.

Some of these meters are classified as data loggers because they record the pressures and temperatures over a period of time. A graph or report can be displayed on the meter or downloaded to a computer. This feature is very important when there is an intermittent problem.

Manifold gauges are available that measure pressure and temperature, calculate superheat and subcooling, and even provide target pressure, temperature, superheat, or subcooling for a particular operating condition. These instruments combine the function of a gauge manifold with the digital superheat and subcooling meters.

23.17 MICRON VACUUM GAUGE

Refrigeration systems must be absolutely free of air and moisture. To ensure that they are free of air and moisture, systems are dehydrated by pulling a deep vacuum on them before they are charged with refrigerant. It is important to measure the vacuum level on the system to determine when evacuation is complete. Micron vacuum gauges are used to measure deep vacuums below the level that a compound gauge on a manifold gauge set can display. The vacuum scale on a compound gauge cannot show the difference between a terrible vacuum and a great vacuum.

Figure 23-40 Subcooling and superheat meter with pressure port and thermocouple. (Courtesy of Fieldpiece Instruments Inc.)

The compound gauge can only show that a vacuum had been pulled down to 29 in Hg. Most manufacturers consider a vacuum level of 500 microns or less the level for a good vacuum. In inches of vacuum, this is 29.9 in Hg. Even if a compound gauge could read this accurately, you could not see it. The needle on most compound gauges is the same thickness as the 1-in Hg vacuum increments. They just cannot show when a good vacuum is achieved. The micron gauge can display vacuums down to around 50 microns. Microns are very small measurements. There are 25,400 microns in 1 inch. The display on micron gauges can show the reading as a number on a numeric display, as in Figure 23-41a, or by lighting an LED next to the micron scale, as in Figure 23-41b. See Unit 30, Evacuation, for more details on using a micron vacuum gauge.

23.18 LEAK DETECTORS

Ideally, no refrigeration system should leak; however, leaks are a major problem with HVACR systems. It is important that all leaks be located and repaired. Electronic leak-detection instruments have made this process much faster, more accurate, and easier. Some leak detectors work better in some locations than others. You should have more than one leak-detection method available.

Figure 23-41 (a) Numeric-display micron gauge; (b) LED-display micron gauge.

Some methods are better for locating the area of a leak and others are better for pinpointing the exact spot of the leak. Applying soap bubbles to a suspected leak is the most common procedure for pinpointing a leak.

TECH TIP

Never use homemade soapy solutions for leak checking. They may be corrosive to the coil or refrigerant piping.

CAUTION

Large leaks of refrigerant in confined spaces are dangerous because they can replace all of the oxygen leading to asphyxiation. If you suspect there is a significant leak, ventilate the area before entering. Equipment rooms with systems that have large refrigerant charges must have self-contained breathing apparatuses available in case of a major refrigerant leak.

23.19 ELECTRONIC LEAK DETECTOR

An electronic leak detector is shown in Figure 23-42. A small pump draws air over a platinum diode located at the end of the test wand.

Electronic leak detectors are capable of detecting leaks as low as 0.4 oz per year. They can be used for HCFC, CFC, and HFC gases. A pump located in the device draws air directly to the sensing tip. No calibration is required. It is battery operated and has both a visual and an audible signal, which increase in frequency as the leak source is approached. Detectors identified as halide leak detectors will only respond to refrigerants containing halogens such as chlorine and fluorine.

If you are looking for a leak in an enclosed space, the leak detector may sense the refrigerant in the air. Calibrate the meter, or adjust its sensitivity to background refrigerant levels, by manually turning the adjustment knob. Some meters calibrate automatically when the technician turns the instrument off and back on.

23.20 ULTRASONIC-TYPE LEAK DETECTOR

An ultrasonic leak detector (Figure 23-43) will detect any gas leaking through an orifice. As refrigerant is escaping from a system, it will generate a sound at a higher than normal frequency. An ultrasonic leak detector can be used to pick up these sound waves. This method works well as long as there are no other sources within the system area that produce sound waves at the same frequency. The ultrasonic leak detector is typically somewhat more expensive as compared to the other leak-detection devices.

Figure 23-42 Electronic leak detectors.

The features and specifications for this meter are as follows:

- Detects pressure or vacuum leaks
- Unaffected by windy, rooftop conditions
- Unaffected by background noise
- Detects ultrasonic noise from arcing electrical switchgear
- Can be used for finding leaks in ductwork

23.21 FLUORESCENT DYE LEAK CHECKING

A small quantity of fluorescing oil is put into the system. Use only oil dyes that have been approved by the equipment manufacturer as safe to use in their system. The system is operated for a period of time. As refrigerant leaks, it takes with it a small quantity of oil. Once a UV lamp shines on the system, even the smallest of leaks is easily found.

The advantages of this leak-detection method are that it can pinpoint leaks, and once the dye is in the oil, rechecking for leaks is easy and fast.

23.22 ELECTRONIC SIGHT GLASS

An electronic sight glass is shown in Figure 23-44. It has both visual and audible bubble detection. Transducer clamps fit tubing from $\frac{1}{8}$ in to $1\frac{1}{8}$ in (3 mm to 32 mm) in diameter. The electronic sight glass uses ultrasonic waves to detect changes in density of the fluid traveling through the pipe. Gas bubbles are much less dense than liquid, so the instrument pings whenever a gas bubble passes in the liquid stream. The electronic sight glass can be used to help diagnose refrigeration problems. The presence of gas bubbles in the liquid line of a refrigeration system can indicate an undercharge. It will also detect liquid droplets in a gas line. Liquid droplets in the low-pressure vapor line can indicate an overcharge.

Figure 23-44 Electronic sight glass.

23.23 DIGITAL CHARGING SCALES

Digital charging scales are used to weigh the amount of refrigerant added or removed from a refrigeration system precisely. They are typically accurate to within 0.25 oz. Most can display weight in kilograms, decimal pounds, and pounds and ounces by pushing the Units button to select the desired units (Figure 23-45). Digital scales can be zeroed with weight on them by pushing the Zero button (Figure 23-46). The scale then displays the amount of weight lost or gained after it is zeroed. This is very helpful during charging or recovery. Scales are available in three general forms: one piece with the platform and display built into a single unit (Figure 23-47), with a removable display attached by a cord (Figure 23-48), or with a cordless removable display (Figure 23-49). Programmable scales are also available with a built-in solenoid controlled by the scale. They can be programmed to shut the flow of refrigerant off after a programmed amount of weight change. You should periodically check your scale with a known weight to ensure that it is accurate (Figure 23-50).

UNIT 23—SUMMARY

Making accurate temperature and pressure measurements is essential to all refrigerant system service. Types of thermometers include glass stem, dial, digital, and infrared. The most common sensors used with digital thermometers are type K and type J thermocouples. Three air temperatures are commonly read when working on air-conditioning equipment: the outdoor ambient temperature, the return-air temperature, and the supply-air temperature. Three types of mechanical pressure gauges are diaphragm, bellows, and Bourdon tube. The Bourdon tube is the most common. The accuracy of mechanical gauges is stated as a percentage. The most accurate mechanical refrigeration gauges are class 1. Digital gauges are more accurate than mechanical gauges. They can show pressures in 1/10 lb. A compound gauge reads both pressure and vacuum; a high-pressure gauge reads only pressure. A gauge manifold set consists of a manifold with a compound and a pressure gauge, valves

to control flow through the manifold, and connecting hoses. Manifolds are available with both three and four hoses and either two or four valves. Refrigerant R-410a requires manifolds rated for its higher pressure. Gauge manifolds and hoses are often color coded: blue for the low-pressure side and red for the high-pressure side. Refrigerant spray can be minimized by using positive shutoff adapters and fittings with the gauge manifold hoses. Deep vacuums are measured using a micron vacuum gauge instead of a compound gauge. Common refrigerant leak detectors include soap bubbles, electronic leak detectors, ultrasonic leak detectors, and fluorescent dye.

UNIT 24

Piping and Tubing

OBJECTIVES

After completing this unit, you will be able to:

1. list the pipe and tubing materials used for air conditioning and refrigeration.
2. discuss the characteristics of copper tubing.
3. describe the characteristics of ACR copper tubing.
4. discuss the methods of joining copper tubing.
5. discuss the characteristics of iron and steel pipe.
6. describe how to thread iron pipe.
7. describe how to cut and join PVC and CPVC pipe.

24.1 INTRODUCTION

Heating and air-conditioning equipment needs refrigerants, fuels, and fluids to operate. All of these travel through piping or tubing, both inside and outside the equipment. Working with the different piping materials is a key component of installing and servicing air-conditioning and refrigeration equipment. Understanding the material properties and connection techniques is essential knowledge for air-conditioning and refrigeration technicians.

24.2 TYPES OF TUBING AND PIPING MATERIALS

In the air-conditioning and refrigeration industry, the most commonly used materials for piping and tubing are copper, iron, steel, aluminum, PVC, and CPVC. The preferred choice of material depends upon the pressure the tubing must contain, compatibility with the chemical it will be used with, ease of working the material, and the cost of the material.

Pipe Versus Tubing

Pipe is always named by its approximate inside diameter and schedule, or wall thickness. This can be confusing because the actual inside diameter is usually slightly larger than the nominal size. In other words, neither the inside nor the outside diameter of $\frac{1}{2}$ -in iron pipe is $\frac{1}{2}$ in. Tubing is usually measured by its outside diameter because the outside diameter of tubing is accurate. This means that $\frac{1}{2}$ -in OD tubing actually measures $\frac{1}{2}$ in. However, tubing sold in hardware stores for water piping is commonly sold by its nominal size, which is its approximate inside diameter. Figure 24-1 shows the difference between $\frac{1}{2}$ -in steel pipe and $\frac{1}{2}$ -in OD copper tubing. This nominal size is arrived at by subtracting $\frac{1}{4}$ in from the tubing outside diameter. Air-conditioning and refrigeration tubing is always specified by outside diameter. Copper tubing suitable for air-conditioning and refrigeration use, whether rigid or coiled annealed, is dehydrated and marked "ACR."

Figure 24-1 Comparison of $\frac{1}{2}$ -in OD copper tubing and $\frac{1}{2}$ -in nominal iron pipe.

Refrigeration Lines

Most refrigeration lines are made of copper. However, lines for ammonia systems are made of steel because ammonia chemically reacts with copper. Aluminum is used for internal piping of some air conditioners and appliances, but it is not used for field piping because of the difficulty in joining aluminum tubing.

Fuel Gas Lines

Black iron is used for piping natural gas. Galvanized iron pipe should not be used for natural gas because of the reaction between the odorant in the gas and the zinc in the galvanized coating. The residue generated by this reaction can migrate into the gas valve. Gas piping is being run in new flexible plastic-covered corrugated stainless steel piping (CSST) (Figure 24-2). This material costs more than black iron but is quicker and easier to run. There are limitations on where it can be used, so even systems run with the new material generally have some black iron pipe. Copper is commonly used for liquid petroleum (LP) gas lines, but it should not be used for natural gas with an average of 0.3 grains of hydrogen sulfide per 100 standard cubic feet

Figure 24-2 Flexible corrugated steel tubing used for gas lines.

(scf) of gas. Hydrogen sulfide found in the odorant added to natural gas reacts with copper. Check with the local building code authorities before using copper on natural gas lines. The flexibility of the aluminum tubing has made it the primary material used for piping the pilot gas for standing pilot systems on both natural and LP gas systems.

Water Piping

Galvanized iron, copper, PVC, and CPVC have all been used for water piping. Black iron should not be used with water because it rusts. Copper was the material of choice for water systems before the advent of PVC and CPVC plastic pipe, which have replaced copper for water lines in most new construction because the material is very inexpensive and is easy to join. Drain lines are usually run in PVC but can be run in CPVC or copper if the drain water is high temperature.

24.3 IRON AND STEEL PIPE

Iron and steel pipe are available in different strengths, called schedules. The higher the schedule number, the stronger the pipe. Available strengths range from schedule 5 to schedule 160. Figure 24-3 summarizes the characteristics of standard iron and steel pipe. The most common schedules used for air-conditioning and refrigeration work are schedules 40 and 80. Another system of strength designation simply refers to the pipe as standard, extra strong, or double extra strong.

1 1/2 XXS	1.900	1.100	0.400	6.41

Figure 24-3 Pipe specifications.

Standard generally equates to schedule 40, and extra strong equates to schedule 80. Double extra strong is somewhat heavier than the highest schedule pipe, schedule 160. Figure 24-4 shows a cross-section comparison of standard, extra-strong, and double-extra-strong pipe.

TECH TIP

The original idea behind pipe schedules was for the schedule number to have a uniform relationship of 1,000 times the pressure-to-tensile strength ratio in the modified Barlow equation that is commonly used to determine how much pressure a pipe can hold. This proved to be impractical, but the schedule numbers remained as a common designation for different strengths of pipe.

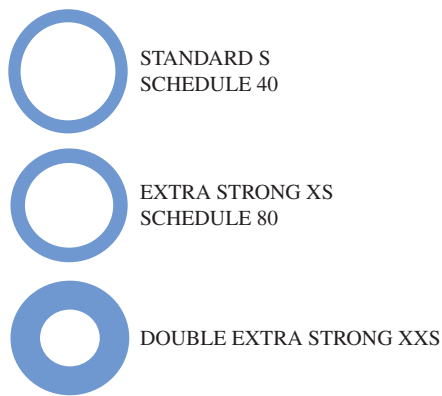

Figure 24-4 Standard, extra-strong, and double-extra-strong pipe are differentiated by their wall thickness.

Figure 24-5 Iron pipe in black and galvanized.

Iron pipe is available in two finishes: black iron and galvanized (Figure 24-5). Black pipe is iron pipe that has its natural finish, while galvanized is iron pipe that has been dipped in molten zinc to make it corrosion resistant. Galvanized has a silver appearance similar to steel. Steel pipe is made from steel, which is made by alloying iron with carbon for added strength. Iron and steel pipe come in 21-ft lengths, threaded on each end. Typically pipe is supplied with a coupling on one end.

Iron pipe is measured by its approximate inside diameter and comes in $\frac{1}{8}$ -in increments from $\frac{1}{8}$ in to $\frac{1}{2}$ in, $\frac{1}{4}$ -in increments from $\frac{1}{2}$ in to $1\frac{1}{2}$ in, and in $\frac{1}{2}$ -in increments from $1\frac{1}{2}$ in and up. The nominal size is the approximate inside diameter, but the actual inside diameter is slightly larger than the nominal size. The most consistent measurement is the outside diameter. The outside diameter is approximately $\frac{1}{4}$ in larger than the nominal size. To determine the size of iron pipe, measure the outside diameter and subtract $\frac{1}{4}$ in. To measure a pipe fitting, measure the threads and subtract $\frac{1}{4}$ in. This applies to both internal and external threads. For $\frac{1}{8}$ -in and $\frac{3}{8}$ -in pipe, the measurement needs to be to the nearest $\frac{1}{8}$ in.

24.4 JOINING IRON AND STEEL PIPING

Iron and steel pipe may be joined by welding, flanges, or threaded connections (Figure 24-6). Flanged and welded connections are only used in large industrial and commercial

Figure 24-6 Examples of welded, flanged, and threaded pipe joints.

applications. Most iron and steel piping used in air conditioning is joined by cutting threads on the end of the pipe and joining the pipe with threaded fittings. Pipe threads are tapered $\frac{1}{32}$ in per inch of threads; they have a slightly larger outside diameter at the end of the threads than at the beginning (Figure 24-7). The first seven threads are fully formed, but the threads at the back are not. The taper allows pipe threads to tighten and seal. The number of threads per inch decreases as the pipe size increases. Figure 24-8 lists the threads per inch for different sizes of pipe.

Pipe sealant is used when assembling the threads to lubricate the threads and help seal the joint. Check the sealant to make sure it is compatible with the gas or liquid that the pipe will carry. Not all sealants are compatible with all gases and liquids. Some pipe sealants specifically warn against using them with LP gas. Pipe sealant should not be

Figure 24-7 Pipe threads are tapered; the starting threads are smaller in diameter than the last threads.

Nominal Size	Threads per Inch
1/8	27
1/4, 3/8	18
1/2, 3/4	14
1, 1 1/4, 1 1/2, 2	11 1/2

allowed to get inside the pipe when assembling it. Insert the male threads into the female threads for a full turn before applying the pipe sealant (Figure 24-9). This will keep pipe sealant out of the inside of the pipe.

Teflon tape can be used as a pipe sealant, but some mechanical and gas codes prohibit its use. Make sure that Teflon tape is acceptable for your application before using it. Teflon tape is applied by wrapping it around the threads in a direction opposite to the direction the pipe will be turned (Figure 24-10). If it is applied in the same direction, it will bunch up when the joint is tightened. Take care not to have tape all the way to the end of the pipe; the first couple of threads should not have tape on them.

Figure 24-10 Teflon tape should be wrapped opposite to the direction the pipe will be turned, leaving the first threads exposed.

Figure 24-11 Portable tripod pipe vise.

24.5 CUTTING AND THREADING IRON AND STEEL PIPE

When installing a piping system with iron pipe, the pipe must be cut and fitted. The cut ends have to be threaded before they can be joined. The pipe is held in a pipe vise while it is being cut and threaded. The most common vises used in the field are tripod vises that can be transported to the job (Figure 24-11). Vises with regular flat jaws cannot hold pipe properly. The jaws of a pipe vise are semicircular, with ridges designed to hold the pipe (Figure 24-12). Manual pipe-threading tools typically include a pipe cutter, a pipe reamer, a ratchet handle, and several die heads that fit in the ratchet handle. The pipe cutter works just like the tubing cutters used on copper; it is just larger. The reamer is used to cut out the burr left from the pipe cutter. The ratchet handle holds the die heads. A typical ratchet handle can accommodate heads for pipe sizes from 1/2 in up to 1 1/4 in. The steps to cut pipe to length and thread it are listed below and shown in Figure 24-13.

1. Mount the pipe in a pipe vise.
2. Cut the pipe to the desired length using the pipe cutter.

Figure 24-12 Pipe vise jaws are designed to hold pipe.

Figure 24-13 Steps in threading iron pipe.

3. Use the pipe reamer to remove the burr left by the pipe cutter.
4. Insert the correct die in the ratchet handle.
5. Apply thread-cutting oil to the pipe.
6. Slide the die over the pipe. Make sure that the end without teeth showing is the end that goes over the pipe first. Also, check the direction of the arrow on the ratchet handle. It should be pointing to the right. If it is not, pull it out and flip it around so that it points to the right.
7. Apply pressure to the die with the heel of your hand while turning the ratchet handle. After one or two full turns it should not be necessary to keep applying pressure.
8. Continue to turn the ratchet handle, stopping every couple of turns to lubricate the threads and die with cutting oil.
9. Continue until the end of the pipe is flush with the teeth on the backside of the die.
10. Flip the arrow on the ratchet handle and turn the ratchet handle in the opposite direction to remove the die head.

Figure 24-14 Common pipe fittings (from left to right): couplings, cap, union, 90° ell, 45° ell, plug, tee, bell reducer, and bushing.

SAFETY TIP

Always wear gloves and safety glasses when handling, cutting, and threading pipe. The chips created by the threading process are quite sharp and can easily cut you.

24.6 PIPE FITTINGS

Iron and steel pipe is most often joined with threaded pipe fittings. Common pipe fittings include pipe couplings, unions, ells, tees, caps, plugs, bushings, and bell reducers (Figure 24-14). Pipe fittings can have either male or female threads; male threads will fit into female threads. To meas-

ure pipe fittings, measure the threads to the nearest $\frac{1}{4}$ in and subtract $\frac{1}{4}$ in. For male fittings, measure the outside diameter of the threads; for female fittings, measure the inside diameter of the threads (Figure 24-15). The measurement is approximate, that is why you measure to the nearest $\frac{1}{4}$ -in measurement. The two exceptions to this rule are $\frac{1}{8}$ -in pipe fittings and $\frac{3}{8}$ -in pipe fittings; they will measure approximately $\frac{3}{8}$ in and $\frac{5}{8}$ in. Two pieces of pipe can be joined by either a coupling or a union. A coupling is a cylinder with female threads on both ends. The coupling threads onto one pipe and another pipe threads into the coupling. One of the pipes being joined must be able to turn in order to use a coupling (Figure 24-16). A union can connect two pipes when neither can be turned. A union, also called a ground joint union, consists of three pieces:

Figure 24-15 The threads on these $\frac{3}{4}$ -in pipe fittings measure 1 in.

Figure 24-16 A coupling can only be used to join two pipes if one pipe can turn.

two threaded ends that each connect to a pipe and a large nut that pulls the two ends together (Figure 24-17). Elbows, often called ells, are used to change the pipe direction. They are available in 90° and 45° (Figure 24-18). Common ells have female threads on both sides. A street ell has one female and one male end. It is designed to fit into another fitting and allow a pipe to fit into it (Figure 24-19).

Figure 24-17 Because a union has three parts, it can join two pipes even if neither can turn.

Figure 24-18 A 90° elbow and a 45° elbow.

Figure 24-19 A street elbow has a female end and a male end.

TECH TIP

The name “street ell” comes from its use in sewage and waste lines. Because waste lines only flow because of gravity, care is taken to minimize restriction. A street ell has both a female and male end. Pointing the male end toward the street in a waste line offers less restriction because the waste products do not get caught on the edge of the pipe as they do with regular ells.

Tees are used when a line must branch off of another line. They are shaped like the letter T and have female threads. Regular tees are the same size at both ends and in the middle. Reducing tees can have different sizes. Reducing tees are specified by the run and branch size. The run is the part straight through the tee; the branch is the side port (Figure 24-20).

Figure 24-20 The run is the part of the tee that goes straight through the tee. The branch is the line coming off the side, like a tree branch.

Use Bell Reducers Instead of Bushings

Two fittings are available for connecting a smaller pipe to a larger pipe: bushings and bell reducers, also called a reducing coupling. A bushing has both male and female threads. It fits inside a larger fitting and allows a smaller pipe to thread into the female threads (Figure 24-21). A bell reducer has female threads on both ends and looks something like a bell because one end is smaller than the other. A large pipe can thread into one end and smaller pipe in the other ends (Figure 24-22).

Caps and Plugs

A cap is used to seal off a threaded pipe. A plug is used to seal the hole in a threaded female fitting (Figure 24-23).

CODE TIP

Most codes require bell reducers rather than bushings for making reductions in size. Bushings increase turbulence and restrict flow.

24.7 COPPER TUBING

There are several grades of copper tubing. It is available in different wall thicknesses and two hardness. Copper tubing comes in rolls or straight lengths and can be standard or dehydrated.

Types of Copper Tubing

Copper is available in three wall thicknesses: K (heavy), L (medium), and M (light). Type K heavy wall tubing is meant for special use where abnormal conditions of corrosion might be expected. Type M thin wall tubing is not used on pressurized refrigerant lines because it does not have the wall thickness to meet the safety codes. It can be used for water lines and condensate drains. Type L is most frequently used for normal refrigeration applications. Figure 24-24 provides specifications for both type K and type L tubing.

ACR Copper Tubing

Copper tubing intended for refrigeration and air-conditioning work is designated as ACR tubing (Figures 24 and 25). ACR tubing is type L that has been dehydrated. ACR tubing is cleaned, degreased, dehydrated, and sealed to keep its

inside clean. It is purged by the manufacturer with nitrogen gas to seal against air, moisture, and dirt and also to minimize the harmful oxides that are normally formed during brazing. The ends are plugged to keep out air and moisture. These plugs should be replaced after cutting a length of tubing.

Copper Tubing Sizes

ACR tubing is measured by outside diameter. The outside diameter of all three wall thicknesses stays the same; $\frac{5}{8}$ -in outside diameter copper tubing will be $\frac{5}{8}$ -in outside diameter regardless of the wall thickness. The inside dimension does change as the wall thickness changes. The approximate inside dimension is given as the nominal size. Since the wall thickness is approximately $\frac{1}{16}$ in, the nominal size is $\frac{1}{8}$ in smaller than the outside diameter. Figure 24-26 compares the dimensions of the three types of copper pipe.

ACR tubing is available in $\frac{1}{8}$ -in increments from $\frac{1}{4}$ in to $\frac{7}{8}$ in and in $\frac{1}{4}$ in increments from $1\frac{1}{8}$ in up. There is an exception: $\frac{5}{16}$ -in copper is often used for the refrigerant lines on household refrigerators and occasionally is used as a liquid line on residential air conditioners. To determine the size of ACR tubing, simply measure the outside diameter of the tubing. To find the nominal size, measure the outside diameter and subtract $\frac{1}{8}$ in.

Soft Copper Tubing

ACR copper tubing is available in two tempers: 50-ft rolls of annealed soft copper tubing and 20-ft straight sections of hard-drawn copper tubing. Soft copper tubing is tubing that has been softened by annealing. Annealing is the process of heating the tubing up to a temperature of 1,300°F and letting it cool. This permanently softens the copper and makes it malleable enough to mechanically form bends and flares in the tubing. Soft copper tubing is used extensively for refrigeration lines in residential air-conditioning systems (Figure 24-27).

Figure 24-27 Annealed soft copper ACR tubing.

Soft copper must be unrolled before it can be used. It is much easier to straighten the tubing while it is still on the roll. The end on the outside of the roll should be held firmly against a flat surface and the coil slowly rolled out (Figure 24-28).

As copper is bent, it will become work hardened. The more it is bent, the harder it becomes. If excessive work hardening has occurred, it may crack or buckle when formed. Work-hardened copper can be reannealed by heating it to a dull red and allowing it to cool. If this is done quickly with a large hot flame, a minimum of oxides will form on the copper tubing. Slow heating can cause excessive oxides, which can cause problems with system operation once installation is complete.

Figure 24-26 The tubing outside diameter is the same for types M, L, and K.

Figure 24-28 To use copper tubing, take the whole roll and unroll what you need from the outside edge across a clean, flat surface.

Figure 24-29 Lengths of hard copper tubing.

Hard Copper Tubing

Hard copper is used extensively in commercial refrigeration and air conditioning systems. Unlike soft tubing, it is hard and rigid and comes in straight lengths (Figure 24-29). Hard copper cannot be mechanically formed; it will crush or buckle rather than bend. It is intended for use with formed fittings to make the necessary bends or changes in direction. Because of its rigid construction, it is more self-supporting and needs fewer supports than soft copper. Sizes range from $\frac{1}{4}$ in OD to over 6 in OD. Hard-drawn tubing comes in standard lengths of 10 ft and 20 ft. It is dehydrated, charged with nitrogen, and plugged at each end to maintain a clean, moisture-free internal condition. The use of hard-drawn tubing is most frequently associated with large line sizes or where neat appearance is desired.

24.8 CUTTING COPPER TUBING

Copper tubing should be cut using a tubing cutter. Tubing cutters are preferable for refrigeration work because they do not generate chips that can get in the system. Tubing cutters also have the advantage of producing a cut that is perpendicular to the length of the tubing, called a square cut. Tubing cutters are available in different sizes to accommodate different sizes of tubing. A standard tubing cutter typically can cut tubing from $\frac{1}{8}$ in OD up to $1\frac{1}{8}$ in OD (Figure 24-30). Larger cutters handle from $\frac{3}{8}$ in up to $2\frac{5}{8}$ in (Figure 24-31). Traditional tubing cutters will not fit everywhere. Smaller cutters are made that make it possible to cut tubing in confined spaces (Figure 24-32).

All these tubing cutters work by rolling a sharp wheel around the outside of the tubing. The wheel scores the tubing as it rolls around it. The cutter must roll around the tubing several times to properly cut; it does not cut through in one pass. The wheel should be adjusted until it contacts the tubing with a slight pressure. Roll the cutter around the tubing, pulling the cutter so that the cutting wheel leads the cut (Figure 24-33). Increase the tension slightly with each rotation by turning the adjusting knob in a clockwise direction. Continue rolling and tightening until the tubing is cut through. Attempting to cut the tubing too quickly will pinch the tubing in and cause constriction. Figure 24-34

compares an improper cut to a correct cut. Even when done correctly, tubing cutters leave a small burr on the inside of the tube. This burr should be removed using the reamer built into the tubing cutter (Figure 24-35).

Most tubing cutters have a groove that can be used for cutting off the flare on a flared piece of tubing (Figure 24-36). This lets the technician cut off a flare with a minimal loss of pipe.

24.9 BENDING COPPER TUBING

Tubing can be bent with accuracy if the right tools are used and care is taken. It is very important not to crimp the tubing because this can restrict the flow of refrigerant. Never get in a hurry when bending tubing.

When using lever- or wheel-type benders, be sure that the groove in the bender is for the size of tubing you are working with. A tool designed for tubing larger than the tubing you are working with will flatten the tubing (Figure 24-37). The work should be done slowly and steadily to avoid buckling or crimping the tubing.

Most lever-type benders have an "R" mark, which will help you determine the distance from the end of the completed bend to center of the pipe. To use the mark, first measure the distance you want from the end of the pipe to the center of the bend after the bend is completed. This mark lines up on the R mark on the bender. On most benders the distance is measured from the right to the R mark (Figure 24-38). Bend the tubing with a slow, steady pull until the degree mark lines up to the desired angle. The dimension of the completed bend should now be correct.

When making several successive bends on one piece of pipe, it is necessary to calculate the total pipe length needed. To do this, you will need to know the radius of the tubing

Figure 24-37 Using the wrong-sized bender can flatten the tubing.

Figure 24-39 The tubing-bender radius.

Figure 24-38 The desired dimension is measured from the right to the R mark.

bender you will be using. The radius is the distance from the center of the bending wheel to the outside of the bending wheel and should be marked on the bender. Because of the many sizes and designs of tubing benders, there is no standard set of radii to remember. The technician must look on the actual tool that will be used (Figure 24-39).

Example Bend Calculation

- **Tubing** 1/2-in OD ACR annealed tubing
- **Bend** 90°
- **Legs** 7 in on one side and 8 in on the other
- **Bender Radius** 1 1/2

The total length of pipe should be the sum of the two straight lengths plus the length of the 90° arc that connects them. First, calculate the actual straight length of each leg. The actual straight length will be the desired leg length minus the radius of the bender. In this example, the actual straight lengths will be 7 in – 1 1/2 in = 5 1/2 in, and 8 in – 1 1/2 in = 6 1/2 in (Figure 24-40).

To calculate the arc length, first calculate the circumference of a full circle with a radius equal to the radius of the tubing bender. In the example, the circumference would be 1 1/2 in × 2 × 3.14. This equals 3 in × 3.14 = 9.42 in. Since a 90° bend is one-quarter of a circle, the arc length is 1/4 of the entire 9.42 in circumference. This is 1/4 × 9.42 in = 2.355 in.

The entire length of tubing needed is 5 1/2 in + 6 1/2 in + 2.355 in = 14.355 in. The 0.355 portion must be estimated to the nearest 1/8 in or nearest 1/16 in. To estimate to the nearest 1/8 in, divide the decimal remainder by 0.125. Therefore, 0.355 would round off to 3/8 in. To estimate to the nearest 1/16 in, divide by 0.0625. Therefore, 0.355 would round to 5/16 in = 3/8 in. In this case, there is no difference.

The total length needed is then 5 1/2 in + 6 1/2 in + 2 3/8 in = 14 3/8 in. A piece of tubing cut to this length, marked correctly and bent with the R mark, will produce a 90° bend with a 7-in leg and an 8-in leg.

Notice that the total required length is actually slightly less than the simple sum of the two center distances, 8 in + 7 in = 15 in. This is because it requires less tubing to make a rounded turn than a square turn. Simply adding the center distance dimensions will yield an approximate length needed to make the bend. If some waste is allowed, the length can be figured in this manner and the excess cut off at the completion of the bend. The estimation method works for bends of 90° or less but does not work for bends over 90° because of the extra length of the arc.

24.10 JOINING COPPER TUBING

Soft copper tubing can be connected in many ways, including compression, flaring, soldering, and brazing. Compression fittings are typically used to connect water lines to icemakers in household refrigerators. They are also used on split-system air conditioners to connect the refrigerant lines to the evaporator and condenser. Soft copper is also connected by flare connections. Flaring is used commonly on refrigeration lines and water lines. Both hard and soft copper may be soldered or brazed together. Soldering and brazing are the only two methods used to connect hard copper tubing.

24.11 SWEAT FITTINGS

Sweat fittings are used with copper tubing when it is soldered or brazed. Common sweat fittings include flare couplings, ells, tees, caps, male adapters, and female adapters (Figure 24-41). Sweat fittings have both male and female ends. The female ends are referred to as solder ends; the male ends are referred to as fitting ends. Solder ends are measured by their inside diameter because they are designed to fit over the tubing. Fitting ends are measured by their outside diameter because they are designed to fit into the solder end of another fitting. A coupling has two solder ends and is used to join two pieces of copper tubing that are the same size (Figure 24-42). A reducing coupling is used to join two different sizes of copper tubing (Figure 24-43). Elbows, or ells, are used to make sharp turns in a copper tubing line. They are available in 90° and 45°. They also are available in both short and long radius. Standard ells have two solder ends. Street ells have one solder end and one fitting end. Figure 24-44 shows different types of

Figure 24-41 Common sweat fittings, including ell, street ell, coupling, tee, reducing coupling, and male pipe thread adapter.

sweat tees. Sweat tees allow one line to branch off of another. They are sized by the run and branch sizes (Figure 24-45). Sweat caps are used to seal off a piece of copper tubing (Figure 24-46). Male and female adapters are used

Figure 24-45 Sweat tee (with run and branch identified).

to connect copper tubing to pipe threads. A male adapter has a solder-type sweat fitting on one end and male pipe threads on the other end. A female adapter has a solder-type sweat fitting on one end and female pipe threads on the other end (Figure 24-47). The solder end of an adapter is measured by its inside diameter, while the pipe thread end is measured like pipe threads.

24.12 SWAGING TECHNIQUES

A swage joint is used to allow two pieces of copper tubing to be joined by soldering or brazing without any fittings. A swaging tool expands the end of a piece of copper tubing so that it will fit over the end of another tube the same size (Figure 24-48). The depth of the cup on the swage should be equal to the diameter of the pipe being joined. Three types of swaging tools are commonly used: tools that hammer in like a punch, tools that work like a flaring tool, and lever-type tube expanders.

Figure 24-48 Swaged copper tubing. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

Figure 24-49 Hammer-style swage tools.

The hammer style is the least expensive and most common. Hammer swages can be sized for each pipe size, or they can be a multi-taper tool that fits many sizes (Figure 24-49). The tubing is held in a flaring block, and it should be high enough in the block that the swage shoulder does not compress against the block. The swage tool is inserted into the tubing and struck lightly with several small taps (Figure 24-50). Large blows will deform and buckle the copper.

The flaring-style swage tool works similarly to flaring but uses a tip that expands the tubing rather than flaring it (Figure 24-51).

The lever-type expander uses cylinders with segments that look like pie slices. When the lever is pulled, the cone slides into the center of the cylinder and the wedges expand outward (Figure 24-52). The lever should be pulled slowly to avoid splitting the copper. Lever tools make consistent swage joints and are easier to use than hammer types, but they are considerably more expensive.

Figure 24-50 The copper is held in a flaring block when using a hammer-type swage tool.

Figure 24-52 Lever-type tubing expander.

24.13 JOINING COPPER TUBING USING COMPRESSION FITTINGS

The compression joint is composed of a compression sleeve, a ferrule, and a compression nut. The copper tubing fits through the nut and the ferrule into the sleeve (Figure 24-53). The nut threads over the sleeve. As the nut is tightened, it squeezes the ferrule around the tubing. The compression of the ferrule around the tubing seals the joint. The sleeve and nut can be reused but the ferrule cannot since it is irrevocably squeezed around the tube (Figure 24-54). To redo the joint, the old ferrule must be cut off and a new

Figure 24-53 Compression fittings, ferrule, and compression nut. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

Figure 24-54 Once the ferrule is compressed, it cannot be removed from the tubing. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

ferrule used. It is extremely important that the tubing is clean and straight where the joint is to be made and that the nut is not overtightened. It is very easy to assemble a leaky compression joint and very difficult to correct one. Compression nuts and ferrules are measured by the diameter of the hole that the tubing slides through.

SERVICE TIP

Compression fittings for use in refrigeration systems are not interchangeable with the compression fittings used in water systems. You should never use compression fittings designed for plumbing on a refrigeration system. Compression fittings were common on air-conditioning installation valves in the 1980s but are not used today in air conditioning.

Figure 24-55 Flared end on copper tubing.

Figure 24-56 The flared end of the copper tube is squeezed between the male and female flare fittings.

24.14 MAKING FLARE JOINTS

A flared piece of copper tubing has a conical appearance, something like the end of a trumpet (Figure 24-55). The flared end of the tubing is squeezed between two brass fittings, which have complementary 45° angles (Figure 24-56). A flaring tool is used to make the flare on the end of the tubing (Figure 24-57).

A good flare starts with properly cutting and preparing the tubing. The tubing should be cut slowly to minimize the burr left by the tubing cutter. There will still be a small burr, which should be removed with a reamer. The tubing is clamped in the flaring block with approximately $\frac{1}{8}$ in above the block (Figure 24-58). The spinner is locked in place over the tubing (Figure 24-59). Put a few drops of refrigerant oil on the spinner before making the flare. The spinner is turned until the flare is formed by pressing the tubing between the spinner and the block. Slide a flare nut to the flared end of the tubing to check the completed flare. The flare should clear the threads of the flare nut but still fill the chamfer (bevel) on the inside of the nut. The flare is too large if it catches on the threads of the nut. The flare is too small if it does not fill the inside chamfer on the nut (Figure 24-60). If

Figure 24-57 Typical flaring tool.

Figure 24-58 Copper tubing loaded in flaring block ready for flaring.

the flare is not the right size, it should be cut off and redone. A good flare does not require thread sealant because the threads are not what is sealing the joint—the flare face is. If the end of the tubing is not properly deburred, the flaring tool will generate a “rolled bead” around the flare, and this will be the only point of flare surface contact (Figure 24-61)

SERVICE TIP

It may be necessary to put the flare nut on the pipe before making the flare. If the pipe has bends, or flares on both ends, it will be impossible to slide the flare nut on after the flare is made. If you forget and flare the tubing before putting the nut on, the only fix is to cut off the flare, put the nut on, and reflare the tubing.

24.15 FLARE FITTINGS

Flare fittings are used to join soft copper tubing that has been flared. Common flare fittings include flare nuts, ells, tees, caps, plugs, unions, and half unions (Figure 24-62). As in pipe and sweat fittings, ells are used to change the tubing direction, unions are used to join tubing, and tees are used to connect three pieces together to form a branch. Flare nuts slip over the outside of the tubing; they are measured by the diameter of the hole in the back of the nut (Figure 24-63). All

Figure 24-61 When the tubing is not correctly cut and deburred, the burr forms a “rolled bead,” which holds the flare off of the flare face, creating a leak.

Figure 24-62 Common flare fittings include flare nuts, ells, tees, caps, plugs, unions, and half unions.

Figure 24-63 Flare nuts are measured by the diameter of the hole in the back of the flare nut.

Figure 24-64 Male flare fittings can be measured by measuring the hole in the fitting and adding 1/8 in.

other flare fittings have a male 45° chamfer that matches the angle of the female 45° chamfer in the flare nut. The easiest way to measure a male flare fitting is by finding a flare nut that fits it and measuring the hole in the back of the flare nut. It is also possible to measure the hole in the male flare fitting and add 1/8 in (Figure 24-64). A flare half union is used to connect soft copper to pipe threads. They are called half unions because one side is flare threads and the other pipe threads. The flare side is measured using flare rules; the pipe thread side uses pipe thread rules. A common use for half unions is connecting copper lines to compressor heads and valve bodies. The pipe thread side is threaded into the compressor, and the copper tubing is connected to the flare side (Figure 24-65).

24.16 MAKING FLARE JOINTS FOR R-410A REFRIGERANT

Operating pressures for systems using R-410a refrigerant are 40–60 percent higher than systems using R-22 refrigerant. Flares for systems using R-410a refrigerant are the same 45° angle as regular flares, but the cone shape on the end is larger. Figure 24-66 shows a comparison between a normal flare and a flare that is R-410a compliant. R-410a compliant flaring tools have a larger chamfer and use an offset roller to make more uniform flares (Figure 24-67).

R-410a compliant flare fittings are not interchangeable with traditional flare fittings. Flare fittings designed for R-410a are heavier wall and have a larger chamfer area to accommodate the increased flare cones.

Figure 24-65 Half unions are often used to connect copper tubing to compressor heads.

24.17 MAKING A DOUBLE-THICKNESS FLARE

A double flare has two thicknesses of metal at the flare face instead of one. This gives the flare more strength. Double flares are more suited for applications where the flared connection will be repeatedly loosened and retightened. The most common application of double flares is on brake lines for cars.

Double flares are made using a double-flare adapter. The adapter folds over the end of the tubing so that there are two layers of copper at the flare face after the flare is formed (Figure 24-68). After the double-flare adapter has been used, it is removed and the flare is finished with the spinner (Figure 24-69). Figure 24-70 shows the steps in making a double-thickness flare.

24.18 PLASTIC PIPE

Plastic pipe is becoming more popular due to its inexpensive price, ease of use, and relative strength. The most common forms of plastic pipe used in air conditioning and refrigeration are PVC, CPVC, and HDPE (Figure 24-71).

Figure 24-68 The tubing is formed into a “mushroom top” by the double-flare adapter. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

Figure 24-69 Completed double flare. (Courtesy of HVAC Department, Terra Community College, Fremont, Ohio)

Polyvinylchloride, PVC, is normally used for cold-water lines and drainage lines. It can withstand high pressures at low temperatures. It should not be used for hot-water lines. In the air-conditioning industry it is primarily used on condensate drain lines. The PVC is connected to the air-conditioning equipment using adapters that have pipe threads on one side and a PVC socket on the other. A male adapter has male pipe threads, while a female pipe adapter has female pipe threads (Figure 24-72).

PVC pipe comes in 10-ft lengths and ranges in size from $\frac{3}{8}$ in to 6 in. PVC and CPVC sizes are nominal sizes, like iron pipe. The nominal size is the approximate inside diameter of the pipe. The size and schedule of PVC and CPVC pipe are stamped all along the pipe length (Figure 24-73). The size of PVC and CPVC fittings is molded into the fitting (Figure 24-74).

Chlorinated polyvinylchloride, CPVC, is more rigid than PVC and can be used for hot-water lines. It can withstand pressures up to 100 psig at 180°F. It is seldom used for drain lines, simply because it is more expensive than PVC.

Figure 24-70 The tubing is first folded inward by the double-flare adapter, and the flare is finished with the spinner. (Images courtesy Ridge Tool Co.)

High-density polyethylene, HDPE, is used for water-distribution systems, underground gas-distribution systems, and large-scale drainage systems. HDPE tubing is not used much in air conditioning and refrigeration, but it is used for the water loops in ground-source heat pump systems.

Figure 24-75 PVC shear produces a clean, square cut; the hacksaw cut produces chips that must be cleaned off before assembly.

24.19 CUTTING AND JOINING PLASTIC PIPE

Plastic pipe can be cut with a fine-tooth saw or a plastic tubing shear. The shear is preferable because it produces a clean, square cut with no chips, shavings, or burrs. Figure 24-75 compares the end of a pipe cut with a hacksaw to one cut with a shear. The shear uses two large, sharp blades to slice through the tubing (Figure 24-76). The shear uses a ratcheting action to produce enough leverage to easily cut through the plastic pipe.

PVC and CPVC are “glued” together. The “cement” used is not a glue in the traditional sense. Instead, it is a solvent that literally dissolves the pipe, allowing it to fuse together.

PVC and CPVC are both very easy to join, and it requires only four simple steps:

1. Clean the pipe to be joined.
2. Prime the pipe.
3. Apply solvent evenly to the primed pipe.
4. Insert the pipe in the fitting and turn it slightly to help spread the cement.

Figure 24-76 Plastic tube being cut by a shear.

If primer is used first to clean the joint and solvent is applied evenly to the joint, PVC and CPVC joints will seldom leak. PVC and CPVC joints cannot be undone. Mistakes must be cut out.

SERVICE TIP

CPVC pipe requires CPVC solvent; PVC solvent will not work with CPVC. Some solvents will work with either, but not all PVC solvents will work with CPVC pipe. Check to make sure the solvent will work with the type of pipe being assembled to avoid embarrassing joint “blowouts” when pressure is applied.

HDPE pipe is most commonly joined by heat fusion. First, a tool is used that squares the ends of the two pieces of tubing to be joined. Next, the ends of the tubing to be joined are heated until the plastic begins to melt. Last, the two pieces are forced together until the melted plastic cools. When done properly, heat fusion makes a very strong joint.

UNIT 24—SUMMARY

The materials most commonly used for piping and tubing in the air-conditioning and refrigeration industry are copper, iron, steel, aluminum, PVC, and CPVC. Copper tubing is available in three wall thicknesses: M, light; L, medium; and K, heavy. Only types L or K may be used for refrigeration lines. ACR tubing is cleaned, dehydrated, and purged with nitrogen. ACR tubing is measured by its outside diameter. Copper tubing is available in two tempers: hard-drawn sticks or annealed rolls. Annealed tubing can be formed; hard-drawn tubing cannot be formed. Soft copper tubing can be joined by compression fittings, flare fittings, soldering, or brazing. Hard-drawn must be soldered or brazed. Iron pipe is available in several strengths, called schedules. The most common strength used is schedule 40. It is available in two finishes: natural black iron and galvanized. Gas lines are run in black iron. The nominal size of black iron pipe is the approximate inside diameter of the pipe. Iron pipe is threaded and assembled with fittings. PVC is used for drain lines on air-conditioning systems. It is joined using a primer and solvent.

WORK ORDERS

Service Ticket 2401

Customer Complaint: Hot Water Pouring out of Broken Joint

Equipment Type: Combination Furnace and Hot Water Heater

A heating and air-conditioning contractor has just installed a new gas-fired combination furnace and hot water heater. The installers had worked with PVC for

drain lines but had never performed any hot water work. They knew to use CPVC instead of PVC, but they did not know that PVC solvent will not work with CPVC pipe. After the system had operated for a short time, one of the joints gave way and water started gushing out. The service technician recognized the problem and repaired the system with the correct solvent.

Service Ticket 2402

Customer Complaint: Poor Cooling

Equipment Type: Split-System Air Conditioner

The split-system air conditioner in a new home is performing poorly. The service technician notices that the lines are bent at a sharp angle where they come out of the wall. Both are kinked. The liquid line is cool just past the kink. The technician realizes that the kinked lines are restricting refrigerant flow, causing the liquid to flash at the kink in the liquid line. The technician recovers the system refrigerant, cuts out the kinked sections, and brazes in elbows to make the sharp turn. After the system is evacuated and charged, it operates correctly with the line kinks removed.

Service Ticket 2403

Customer Complaint: LP Gas Leak

Equipment Type: 80 Percent LP Gas Furnace

A customer calls and says that she smells gas near the furnace, which was installed last year. The technician arrives and checks for leaks around the furnace. The threaded joint where the gas line enters the gas valve is leaking. The technician recognizes the color of the pipe sealant and remembers that that product is not listed for use with LP gas. The joint is redone with thread sealant that is listed for LP gas.

Service Ticket 2404

Customer Complaint: Deer Cooler Not Cooling

Equipment Type: Field Assembled Walk-in Cooler

A hunting club calls a refrigeration mechanic to look at their deer cooler. They built the deer cooler themselves and hired someone to install it on the weekend in exchange for hunting privileges. The initial installer has not been able to make the cooler work correctly and has said that the equipment is faulty. Everything is running, but the compressor is hot and the suction pressure is very low. There is frost on the expansion valve, but the evaporator is not even cool. The technician recognizes that there is a restriction at the metering device. Looking at the copper tubing used for the refrigeration lines, the technician notices that it is hard copper, type L, $\frac{3}{4}$ -in nominal size. It does not say that it is ACR tubing. The hunting club members confirm that the copper came from a hardware store that one of them manages.

The technician explains that ACR tubing is cleaned and dehydrated, which plumbing tubing is not. There was probably moisture in the tubing that is causing the system to freeze up at the expansion valve. The technician recovers the refrigerant, installs a large filter drier and a moisture indicator in the liquid line, evacuates the system down to 500 microns, and recharges the system with clean refrigerant. The system works for now, but the technician explains that the drier may need to be changed a few more times before all the water is removed.

Soldering and Brazing

OBJECTIVES

After completing this unit, you will be able to:

1. describe the proper clothing and PPE that must be worn during soldering and brazing.
2. explain the difference between soldering, brazing, and welding.
3. list the types of torches used for soldering and brazing.
4. list safe handling procedures for acetylene cylinders.
5. list safe handling procedures for oxygen cylinders.
6. explain the correct procedure for soldering.
7. explain the correct procedure for brazing.
8. explain the correct procedure for nitrogen brazing.

25.1 INTRODUCTION

Soldering and brazing are essential skills for HVACR technicians. Soldering and brazing are required for a wide range of service and installation procedures. For example, technicians frequently fabricate piping systems by soldering or brazing the piping components together. Replacing most refrigeration components requires brazing. Soldering and brazing are skills that require practice to become proficient. Making high-quality, leak-free brazed joints is essential, because refrigerant leaks are a problem that often plague HVACR systems. Leaks can often be traced to a field-brazed joint made during installation. Soldering, brazing, and welding all refer to methods of joining metal parts using molten metal. The processes of brazing, soldering, and welding are often misunderstood as all being the same. In the process of welding, the base metal itself is melted as additional metal from the filler is added to the joint. However, during brazing and soldering, only the metal being added to join the base parts is melted. The difference between brazing and soldering is temperature. Soldering takes place at a lower temperature than brazing, but other than that both processes are similar.

25.2 PPE FOR SOLDERING AND BRAZING

Personal protective equipment, PPE, is specialized clothing or equipment worn by workers for protection against health and safety hazards. When using torches, technicians need protection from potential hazards created by the flames: heat, ultraviolet light, sparks, and molten metal. The wrong apparel can increase the hazards to the technician by igniting.

Clothing

The hazards from heat, sparks, and molten metal can be minimized by wearing flame-resistant clothing that covers the technician's exposed skin. This is especially important when welding because of the large quantity of hot sparks produced by most welding processes. One hundred percent cotton treated for flame resistance or leather clothing is the best material to wear while soldering, brazing, or welding. Synthetic

materials, such as nylon or polyester, should never be worn while soldering, brazing, welding, or cutting because they burn easily. Remember that plastics are made from petroleum products. Shirts worn while using torches should have long sleeves and either have no shirt pocket or have flaps that cover the pocket to prevent sparks from collecting (Figure 25-1). They should have a collar and be able to be buttoned securely around the neck. One hundred percent cotton blue jeans are ideal pants for working with torches. Leather shoes with high tops are preferable because they resist burns from sparks and molten metal (Figure 25-2). Tennis shoes should never be worn when soldering, brazing, or welding. Properly worn protective clothing will prevent burns from sparks, molten metal, and UV light given off when welding.

HVACR technicians often wear work gloves when soldering or brazing (Figure 25-3a). For welding, leather gauntlet-type welding gloves are preferred (Figure 25-3b). The gauntlet keeps both sparks and welding light from burning your exposed wrists.

Safety Glasses

Safety glasses must be worn at all times when using torches to protect the technician's eyes from harmful radiant energy,

Figure 25-1 Shirts should be 100 percent heavy cotton. Pockets should have flaps to keep out sparks.

Figure 25-2 Welding boots should have smooth toes to prevent sparks from being trapped.

Figure 25-3 (a) Work gloves may be cloth, leather palm, or all leather; (b) welding gloves are gauntlet-type gloves with high cuffs.

flying sparks, and molten metal. The level of radiant energy produced increases as the process temperatures increase. The most damaging radiation produced is ultraviolet radiation. UV light can cause skin burns similar to sunburn. These burns can occur very quickly to any unprotected skin surface or the eyes because of the intensity of the arc light. Soldering produces very little UV light, while welding produces a great deal of UV light. That is why a welder's safety shield must be worn over the face at all times when arc welding. Safety glasses intended for use with torches come in different shades, from 1.3 for the lightest shade and least protection to 14 for the darkest shade and highest level of protection (Figure 25-4). In general, the highest level of shade that allows the technician to see the work should be chosen. OSHA recommends a minimum shade of 2 for soldering, 3 for brazing, and 5 for gas welding and cutting. Carbon arc welding requires the highest level of protection, level 14. Table 25-1 shows OSHA shade recommendations for different uses.

25.3 TYPES OF TORCHES

A torch is the primary tool required for soldering and brazing. There are many types of torches, each with its own advantages and disadvantages. The two factors affecting torch operation are the type of fuel used and the oxygen source used. Since some types of fuel have higher heat content than others, the type of fuel used will have a bearing

Figure 25-4 Safety glasses are available in different shades. The same flame viewed through two different glasses shows how much more light the darker glasses filter out.

on the temperature range in which the torch can operate. The way the fuel is stored and delivered depends on the physical characteristics of the fuel. In addition to the type of fuel, the manner in which oxygen is mixed with the fuel will determine the speed with which the fuel can be burned and, thus, the temperature that the torch can achieve. It is important to understand the torch characteristics to achieve good results in soldering. Generally, torches fall into three categories: air fuel, swirl-tip air fuel, and oxygen fuel.

Air-Fuel Torches

Air-fuel torches aspirate air into the tip utilizing the natural draft created by the flow of fuel as it travels through the tip.

The fuel and air are mixed by the venturi action of the tip so that the mixture is ready to burn when it is delivered out the end of the tip. Since the air is only 21 percent oxygen, torches that receive their oxygen by aspirating air are limited in the speed that they can burn the fuel. Therefore, air-fuel torches burn with a relatively cool flame compared to torches that have their own oxygen supply. Air-fuel torches are good for soft soldering because they get hot enough to quickly heat the copper pipe, yet they stay cool enough to prevent oxidizing and burning the pipe. Common fuels used in air-fuel torches include propane, MAPP, and acetylene.

Air-Fuel Swirl-Tip Torches

Standard air-fuel torches will usually not reach temperatures high enough for brazing. Swirl tips create a higher burning temperature for brazing by drawing more air into the tip to mix with the fuel, much like a turbo charger on an engine. While standard air-fuel tips aspirate air near the base of the tip, swirl tips aspirate the air close to the tip (Figure 25-5). Swirl tips are generally available for air-acetylene and air-MAPP torches. Swirl-tip torches usually make a loud whistling sound because of the higher volume of gas and air drawn into the tip. Swirl-tip torches do make brazing possible at a relatively low equipment cost because they do not require a separate oxygen tank and regulator. Figure 25-6 shows a typical swirl-tip torch set for acetylene.

Oxyacetylene Torches

Oxyacetylene torches produce a hotter and more concentrated flame than air-acetylene torches because they use pure oxygen to burn the fuel. Even the coolest oxyacetylene flame is much hotter than an air-acetylene flame. Oxyacetylene torches use an acetylene cylinder, an oxygen

Figure 25-7 Oxyacetylene torch outfit.

cylinder, regulators for each cylinder, connecting hoses, and a torch handle that mixes the acetylene and oxygen (Figure 25-7). They are generally preferred for brazing due to their higher temperature and heating capacity. Oxyacetylene outfits are more expensive and more difficult to transport, but they provide a solution to high-temperature brazing even on larger pipes, where swirl-tip air-acetylene torches won't work. The most common torches used in HVACR service are small portable oxyacetylene brazing torches (Figure 25-8). Larger tanks are typically used for large installations where technicians will be brazing all day long (Figure 25-9).

25.4 ACETYLENE CYLINDERS

To store enough acetylene to make acetylene cylinder storage feasible, acetylene is compressed into the cylinder under a pressure of 250 to 275 psig. However, acetylene gas is unstable under high pressure and can explode just

from being struck or jarred severely. For this reason, the acetylene gas must be stabilized in the cylinder with liquid acetone. The acetone is capable of absorbing 28 times its own weight in acetylene gas. Acetone reacts with acetylene similarly to carbon dioxide and water. Carbon dioxide can be dissolved in water, forming a carbonated beverage. As the pressure on a carbonated drink bottle is slowly released, you can observe bubbles being formed within the liquid. These bubbles are CO_2 gas being released. The acetone in an acetylene bottle works the same way. To prevent the acetone from simply being poured out accidentally, the acetylene cylinder is filled with an absorbent, coarse material during manufacturing (Figure 25-10). The acetone is stored inside a porous material that soaks it up like a sponge. When the valve is opened, the pressure inside the

tank drops and the acetylenes boil out of the acetone. When all the acetylene has boiled out of the acetone, a qualified compressed gas dealer refills the tank. Acetylene tanks come in several sizes, from small tanks that hold 10 ft^3 to large tanks that hold 420 ft^3 . Table 25-2 shows the most

common sizes of acetylene tanks available. Types B and MC are the most popular for portable air-acetylene torches and small oxyacetylene torches (Figure 25-11).

CAUTION

Acetylene cylinders must be used only in the upright position to prevent the acetone from being pulled out of the cylinder with the acetylene. If the acetone comes out, a concentrated, sooty flamethrower-type flame leaves the torch tip. The space left inside the cylinder by the lost acetone can fill with acetylene gas, creating an explosion hazard.

CAUTION

Acetylene cylinders must be secured during storage, transport, and use. Rough handling and banging the cylinder around can damage the filler inside the tank, creating a dangerous acetylene gas pocket that can lead to an explosion hazard.

CAUTION

Acetylene can become unstable and explode at pressures above 15 psig. Because of acetylene’s instability, it is against OSHA regulations to operate a torch with an acetylene pressure greater than 15 psi. Most acetylene gauges have a red warning mark indicating 15 psi (Figure 25-12).

25.5 AIR-ACETYLENE TORCHES

HVACR technicians often use air-acetylene torches for soldering and light brazing. These torch flames are ideal for soldering. An air-acetylene flame burns at a temperature of approximately 4,220°F. Air-acetylene torches work very well for soldering copper pipe from 1/4 in up to 4 inches. Figure 25-13 shows a typical air-acetylene torch.

Figure 25-11 (a) The MC acetylene tank holds 10 ft³; (b) the B acetylene tank holds 40 ft³.

Figure 25-12 Acetylene regulator with gauges.

Figure 25-13 Typical air-acetylene torch.

Figure 25-14 Before opening the acetylene cylinder, the regulator should be adjusted out counterclockwise to relieve the spring pressure on the diaphragm.

Adjusting the Torch

First, check to see that the regulator is adjusted all the way out counterclockwise (Figure 25-14). The cylinder valve should not be opened with the regulator adjusted in, because the sudden cylinder pressure can damage the regulator. Some cylinders have hand wheels, and others just have square stems that require a wrench, as in Figure 25-15. OSHA requires that a nonadjustable wrench be used on any valve stems that are not equipped with a hand wheel (Figure 25-16). The wrench must be left on the cylinder valve anytime the valve is open. Hold the cylinder steady with one hand while turning the valve counterclockwise one-quarter to one-half turn with the other hand (Figure 25-17). Opening the valve a minimum amount will allow you to shut down the valve quickly in an emergency. Do not leave the torch unattended with the valve turned on. If you must leave the work area, secure the torch out of the way of traffic, close the valve, and take the valve key off the stem.

Figure 25-15 Some acetylene cylinders have a hand wheel; others have a square stem.

Figure 25-16 Nonadjustable wrench for acetylene cylinder with a square stem.

Figure 25-17 Support the cylinder with one hand when turning on the acetylene or oxygen valves.

CAUTION

It is against federal regulations (OSHA) to open any acetylene cylinder valve more than two and a half turns. This is to allow you to turn off the cylinder quickly in an emergency. The best practice is to always open the cylinder valve the minimum amount necessary to see a pressure reading on the regulator. Often a half turn will work.

Figure 25-18 (a) Correct position for striker, off to the side of the torch tip; (b) improper position for striker, directly in front of the torch tip.

An air-acetylene torch tip is designed for a specific pressure and flame size. The correct adjustment will depend on the tip being used. Adjust the regulator in clockwise according to the manufacturer’s instructions. The fuel delivery should be adjusted at the regulator, not by the valve on the torch handle.

Lighting the Torch

With the pressure adjusted properly according to the manufacturer’s recommendations for that torch tip, light the torch by opening the valve on the torch body completely and creating a spark at the torch tip with a torch lighter or sparker. The only safe devices to use to light any torch are those specially designed for that purpose, such as spark lighters or flint lighters. Never use household lighters! When using a flint lighter, hold it slightly off to one side of the torch tip, as in figure 25-18a. Do not hold it directly over the tip, as in Figure 25-18b. To shut off an air-acetylene torch, just turn the valve on the handle clockwise until the gas flow stops.

SERVICE TIP

Holding the striker over the end of the tip may cause a pop when the torch is lit.

CAUTION

Never use a cigarette lighter to light any torch. The torch flame can instantaneously burn through the plastic lighter, causing it to explode. Butane cigarette lighters can explode with the force of a quarter stick of dynamite if they are ignited by the torch. The only thing preventing an explosion is a cheap piece of plastic.

The flame should be a quiet, blue flame (Figure 25-19a). If the flames burn away from the tip or try to light but seem to “blow out,” reduce the pressure on the regulator. Gas pressure that is too high will prevent the torch from lighting correctly. If the torch does not light and you can’t hear gas escaping from the tip, turn the regulator clockwise a little at a time until you can hear the sound of acetylene escaping from the torch tip.

Figure 25-19 (a) Correct appearance of acetylene flame; (b) too much acetylene causes a noisy flame that lifts off the tip.

You can control the size of the flame somewhat by using the regulator to control the gas pressure delivered to the torch tip. However, each tip is designed for a narrow range of operating pressures. If the gas pressure to the tip is too low, the torch tip can become overheated. In some severe cases, the tip may actually begin to glow red hot. Do not adjust the flame size to a point where it lifts off the tip and burns with a loud rushing sound, Figure 25-19(b). The best way to either increase or decrease the amount of heat the torch produces is to change the size of the torch tip. Tip size can be important since the success of a soldered joint depends largely on the manner in which heat is applied to the joint. The air-acetylene tips available from one manufacturer are listed in Table 25-3. Note that the #1 tip is for soldering up to ¼-in tubing, while #6 is needed for soldering 4-in tubing.

Putting up the Torch

When you are finished with the torch, shut the valve on the tank off (clockwise), and remove the valve key. Open the handle valve and bleed the gas out of the handle and regulator. Turn the regulator counterclockwise until you

feel the spring tension let up. This prevents a sudden surge of pressure on the regulator diaphragm when the torch is used next. Finally, secure the torch in the designated storage area. Acetylene cylinders and torches should be stored away from flammable materials or oxygen cylinders in a well-ventilated area that is protected from the weather. They should be stored in the upright position and physically restrained to prevent being tipped over.

25.6 SOLDERING

Soldering is used in the HVAC industry to both join electrical wiring and components and for copper pipes when used for water or condensate drains. Soldering is not approved by most manufacturers or codes for use in refrigerant lines or combustible gas lines. Electrical soldering is accomplished using an electric soldering iron. Soldering to join copper pipes is accomplished with an air-acetylene torch, air-MAPP torch, or air-propane torch. Oxyacetylene torches are not recommended for soldering because their flame temperature is so high that the pipe is easily overheated. When overheating occurs, the flux breaks down and excessive oxides are formed so that no bonding can occur.

In both brazing and soldering, the base metal must be heated to a temperature where the bonding phase between the liquid filler and the base metal can occur. This process is called tinning. The soldering alloy must be able to chemically bond with the metals being soldered. The solder forms an alloy with the base metal when the molecules of the solder enter and fill spaces existing between molecules of the base metal. For the bonding or tinning phase to occur between the filler metal and the base metal, often a flux is required (Figure 25-20). A flux is an active compound that removes light surface oxides and promotes the wetting of the base metal with the liquid filler metal. If the metal is oxidized, the solder will not stick because the oxide is already filling the spaces between molecules. Flux prevents the formation of oxides during the heating process, keeping the spaces open for the solder. If the metal being joined is too cool or too hot, tinning cannot occur. Overheating is a major problem when brazing or soldering copper pipe because the flux will burn (become oxidized), stop working, and become a barrier to tinning. In addition, a heavy oxide can be formed on the pipe itself, preventing a bond forming between the filler metal and the pipe surface.

Figure 25-20 Soldering paste flux.

Soldering Alloys

Soft solder is generally a combination of two metals. Older solders were often made of tin and lead. One common alloy, 50 percent tin and 50 percent lead, was used for plumbing. Lead solders are no longer used in plumbing because of the health concerns with lead. An alloy of 95 percent tin and 5 percent antimony is more common now. One problem with 95/5 is that it can become brittle and crack from vibration. A solder alloy called silver-bearing solder is often used where vibration is a concern. It is 96 percent tin and 4 percent silver. Table 25-4 illustrates some of the characteristics of common soldering and brazing alloys.

Preparing the Joint

Begin by cleaning the copper pipe and fitting using abrasive cloths like those shown in Figure 25-21. A wire brush or sand cloth may be used to remove any contaminants, such as oxidation, oil, paint, or dirt. Do not touch the part to be soldered with your hand. Oil from your fingers can prevent solder from flowing completely into a joint. The cleaned end should look like Figure 25-22.

(b)

(c)

Figure 25-22 (a) Copper pipe before cleaning; (b) copper pipe after cleaning; (c) clean at least $\frac{1}{2}$ in beyond the fitting.

With the joint clean, use a brush to apply the flux. Do not apply flux to the very end of the pipe; you don't want any flux in the pipe after it has been soldered. Apply the flux up to approximately $\frac{1}{16}$ in to $\frac{1}{8}$ in from the end of the pipe, as shown in Figure 25-23. This will help prevent flux contamination into the system. Insert the flux-covered pipe into the copper fitting and twist the copper pipe inside the copper fitting to spread the flux around inside the joint.

Heating the Joint

During soldering, the molten solder runs toward the heat. Uniform heating of the joint is important to provide uniform solder coverage and completely fill the joint with the solder alloy. It is important to understand that the torch is not used to directly melt the solder. To ensure that both the base metal and the solder are hot enough to bond, the torch should only be used to heat the metal and

Figure 25-23 Apply the flux up to approximately $\frac{1}{8}$ in from the end of the copper pipe.

Figure 25-24 Preheat the pipe before moving the flame over the fitting.

the metal should melt the solder. Begin heating by heating the pipe first. As the pipe expands, it will make firm mechanical contact with the inside of the copper fitting (Figure 25-24). This mechanical contact will aid in capillary attraction, which pulls the solder into the joint. The mechanical contact also aids in thermal conductivity so that the entire pipe and joint become uniformly heated. As the pipe begins to heat up, move the flame onto the fitting and pipe. Periodically test the backside of the joint with the tip of the solder. Once the solder begins to flow freely, remove the torch. Continue adding the solder until you see a silver ring all the way around the joint (Figure 25-25). Ideally, a small fillet of solder should be left at the joint surface (Figure 25-26).

To prevent overfilling of the joint, before you start, bend the solder to match the diameter of the pipe being soldered. A length of solder equal to the diameter of the pipe being soldered is adequate to make soldered joints in most copper lines smaller than 1 in diameter (Figure 25-27).

Figure 25-25 Add solder until silver ring appears all the way around the joint.

Figure 25-26 Add a small amount of additional solder to create a fillet around the joint.

Solder will not stop flowing into the joint. If you continue to heat the joint and feed more solder, it will continue to go in. Pushing more solder into the joint simply results in solder BBs being formed inside the piping system. In the field, these BBs of solder can circulate back to water pumps where they can cause damage to the pump's impellers. In extreme cases the line can become completely blocked with solder (Figure 25-28).

Figure 25-27 A length of solder equal to the pipe diameter is all that is needed.

Figure 25-28 Too much solder was fed into this joint, resulting in solder inside the pipe.

SERVICE TIP

When soldering copper pipe, once the metal has been overheated you must stop to cool and reclean the parts before the joint can be made correctly. If the parts are not disassembled and recleaned, only the outside of the joint will be able to be joined. This will leave a joint that will someday leak.

Testing Soldered Joints

Once the solder joint has been completed, allow it to cool before cutting a slice into the pipe fitting at approximately a 45° angle using a hacksaw (Figure 25-29). Use a slight rocking motion as the cut progresses, so that you are only cutting through the fitting and not the pipe (Figure 25-30). Figure 25-31 shows what the cut should look like when it is done. To release the fitting from the copper pipe, put the tip of a flat-blade screwdriver into the slot, apply pressure, and twist (Figure 25-32). Using a pair of pliers, peel back the copper fitting, exposing the soldered surface. If the surface is smooth and has no large voids, the soldering job was successful (Figure 25-33). Some small flux-filled pockets may remain. These voids are acceptable as long as they do not

Figure 25-29 The first step in testing a solder joint is to make a hacksaw cut diagonally across the fitting.

Figure 25-31 The finished cut should completely cut through only the outer fitting. A small cut into a portion of the inner fitting is OK.

run from near the inside of the joint to near the outside. Obviously, this test will render the joint unusable. The technician may use this test for the practice and development of brazing skills.

Overheating and under-heating are common problems with soldering. Overheating is indicated by tiny bubbles in the solder (Figure 25-34). The bubbles are formed as the solder boils. Under-heating is indicated if the solder does not flow into the joint. If the joint were heated first instead of the pipe first, then during soldering the pipe would separate

Figure 25-33 An acceptable solder joint is one that will have a minimum amount of small bubbles and flux inclusions.

Figure 25-35 From the outside, this joint looks very good; solder flowed completely across the outside face of the joint, indicating that the fitting was at the proper soldering temperature.

so that heat would not transfer to the pipe from the joint. The solder on the outside of the joint may look great, as in Figure 25-35. In Figure 25-35, the solder not only flowed around the joint but even down the outside. But looking at the inside of the joint in Figure 25-36, we see that the solder penetration was actually very poor. The solder did not flow throughout the joint space and left large unfilled voids. This can be caused by inadequate joint temperature or a swage joint that is uneven.

25.7 OXYGEN CYLINDERS

Oxygen is stored in the cylinder as a compressed gas. Unlike acetylene cylinders, there is nothing inside an oxygen cylinder to absorb the oxygen. Compressing a large volume of oxygen gas into a cylinder creates tremendous

internal cylinder pressure. A full oxygen cylinder contains approximately 2,000 psig of oxygen. All high-pressure cylinders that can be transported on public roads must meet federal Department of Transportation (DOT) guidelines. The cylinders must be marked with the cylinder specification, serial number, manufacturing date, owner, retest markings, and tare weight (Figure 25-37).

Since high-pressure, pure oxygen will burn anything that is even marginally combustible, the least piece of trash in the oxygen regulator can cause a fire that can burn up the regulator's diaphragm. Oil and pure oxygen under pressure can spontaneously combust. The ensuing explosion can be lethal. Even small quantities of oil that may get on the oxygen gauge, valve, or hoses can cause an explosion when

subjected to high-pressure oxygen. It is very important that you never allow oil to come in contact with oxygen and acetylene equipment.

CAUTION

Use no oil or thread sealant on the threads of the oxygen regulator. Go to extreme measures to keep the oxygen-delivery system clean.

Oxygen cylinders should always be stored and transported with their safety caps in place. The safety cap screws over the cylinder valve to prevent physical damage to the valve (Figure 25-38). The regulator and torch assembly must be removed from the cylinder to install the safety cap. Oxygen cylinders are available in sizes for 20 ft³ to 400 ft³ (Table 25-5). Two common cylinder sizes used for

Table 25-5 Oxygen Cylinder Sizes

20 ft ³	5 × 14 in	15 lb
40 ft ³	7 × 17 in	25 lb
55 ft ³	5 × 41 in	25 lb
80 ft ³	7 × 36 in	53 lb
125 ft ³	7 × 48 in	79 lb

the air-conditioning and refrigeration trades are the 20 ft³ and the 55 ft³ cylinders (Figure 25-39).

CAUTION

Federal safety regulations (OSHA) require 55 ft³ cylinders and larger to be safety chained to a cart or structure anytime the cylinder valve cap is removed. If one of these high-pressure cylinders falls over and the valve breaks off, the cylinder will be propelled through the air like a missile. The force is enough to break through concrete-block walls.

CAUTION

Always remove regulators from oxygen and acetylene cylinders before you put them back in your service vehicle. In many states and cities it is against the law to transport oxygen and acetylene cylinders in a motor vehicle with the regulators attached. The danger is that in an accident the regulators could be broken off, causing a fire or explosion.

CAUTION

Compressed oxygen should never be used in place of nitrogen or compressed air. If oxygen were used to pressurize a refrigeration system and the system were started, there would be a severe explosion of the compressor and compressor shell. This explosion would be hazardous to anyone within the immediate area.

25.8 OXYACETYLENE TORCHES

The oxyacetylene flame is often required to make braze joints in large refrigerant lines and join refrigerant lines to compressor stubs. An oxyacetylene torch requires an acetylene cylinder, an oxygen cylinder, a regulator for each cylinder, a torch handle that mixes the oxygen and acetylene before delivering the combustible mixture to the tip, and a set of hoses to connect the regulators to the handle. Oxyacetylene torches have changeable tips whose size helps determine the temperature of the flame. Figure 25-40 shows a typical oxyacetylene torch kit.

Figure 25-40 Typical large oxyacetylene torch setup.

Figure 25-41 The oxygen regulator connects to the cylinder with a female, right-handed thread.

It is extremely important that the two hoses and regulators not be mixed up and connected to the wrong type of gas. Connecting a regulator that has acetylene in it to a high-pressure oxygen cylinder would cause the regulator to explode. Oxyacetylene equipment is designed to prevent this. The oxygen regulator connects to the cylinder with a female, right-handed thread (Figure 25-41). The oxygen hose is green and connects to both the regulator and torch handle with right-handed threads (Figure 25-42). The acetylene regulator connects to the acetylene cylinder with a male, left-handed thread. The acetylene regulator has hash marks that indicate it has left-handed threads (Figure 25-43). The acetylene hose is red and connects to

both the regulator and the torch handle with left-handed threads. The left-handed threads are indicated by the hash marks (Figure 25-44).

The regulators have two pressure gauges: one for tank pressure and another for regulated pressure (Figure 25-45). Turn the T handle in clockwise to increase the regulated pressure. Turn the T handle out counterclockwise to decrease the regulated pressure (Figure 25-46).

Figure 25-46 Turn the T handle in clockwise to increase the pressure (red arrow). Turn out counterclockwise to decrease the pressure (blue arrow).

SERVICE TIP

The intense oxyacetylene flame heats up parts faster than air-acetylene flames. This concentrates more heat on the work, allowing braze joints to be completed faster. Spending less time heating the parts reduces the amount of heat conducted to surrounding parts that might be damaged by the brazing heat. Although it sounds counterintuitive, the hotter flame can reduce the amount of heat damage done to connected components if it is used properly.

Adjusting the Torch

First, check to see that the regulators on the acetylene and oxygen cylinders are not adjusted in. They should both be out counterclockwise until there is no spring pressure on the T handle (Figure 25-47). Stand behind the acetylene cylinder on the side opposite the regulator so that you are not in a direct line with the regulator. This reduces the possibility of being struck by the regulator should it fail and come flying apart under pressure. Using the tank valve key, turn the acetylene tank valve counterclockwise the minimum amount required to get a reading on the cylinder pressure gauge. This should never be more than two and a half turns. Make sure to leave the key on the valve while you are using the torch.

Stand behind the oxygen cylinder on the side opposite the regulator so that you are not in a direct line with the regulator and crack open the valve counterclockwise (Figure 25-48).

Figure 25-47 Regulators should be out counterclockwise before opening cylinder valves.

Once you see a reading on the oxygen cylinder pressure gauge, open the oxygen tank valve all the way counterclockwise. This is done to prevent the high cylinder pressure from placing a strain on the cylinder valve threads.

Torch manufacturers have designed their equipment to operate properly at specific acetylene and oxygen pressures. Always consult the manufacturer's tip chart when determining the correct pressures for adjusting an oxyacetylene torch. Table 25-6 shows a typical brazing tip chart. Regulate the acetylene and oxygen pressures by slowly turning the regulators in clockwise and observing the pressure gauges. Brazing seldom requires acetylene pressures greater than 8 psig, and any acetylene pressure adjustment beyond 15 psig is extremely dangerous. Do not exceed the recommended pressure for any given torch and application.

CAUTION

The acetylene and oxygen should never mix anywhere in the torch assembly except in the carburetor and tip. A condition known as reverse flow can occur if unequal acetylene and oxygen pressures are allowed to mix in the hoses, regulators, or cylinders. In a worst-case scenario, reverse flow can result in a catastrophic explosion. To avoid reverse flow, you should keep your equipment in good condition, never use an oxygen cylinder with less than 50 psig in it, always independently bleed each hose before lighting the torch, and never light both gases at once.

Lighting the Torch

To prevent potentially dangerous backfires in the torch, acetylene is always ignited first and turned off last. When lighting an oxyacetylene torch, ignite the acetylene without

the oxygen and then add the oxygen to produce a neutral flame. When shutting the torch down, shut off the oxygen first and the acetylene last. To light the torch, open only the torch handle acetylene valve slightly and light the acetylene gas using a spark or flint lighter. This should produce an orange and slightly sooty flame. After the torch lights (Figure 25-49a), increase the flow of acetylene until most of the smoke in the flame has disappeared (Figure 25-49b). Next, slowly open the oxygen valve counterclockwise (Figure 25-49c). Increase the oxygen flow until the center cone is well defined and the feather completely disappears and joins the center cone (Figure 25-49d). This is a neutral flame. Do not increase the oxygen flow rate beyond this point. Further increasing the oxygen will produce an oxidizing flame (Figure 25-49e). Oxidizing flames burn up the work and cause excessive oxides to form on copper during brazing. A properly adjusted oxyacetylene flame will burn with a balanced, or neutral, flame. This means there is not an excess of oxygen or acetylene. It is important to use a balanced or neutral flame so that the flame does not introduce contaminants into the braze joint.

CAUTION

The oxygen cylinder valve should be opened slowly to prevent a sudden compressive force on the regulator from the high cylinder pressure. Sudden high pressure can create heat. If there is an explosive mixture in the regulator, heat from opening the oxygen cylinder quickly can ignite the mixture and cause an explosion.

Adjusting the acetylene flow rate so that most of the smoke disappears will ensure that you have adequate gas flow to keep the tip cool. If there is insufficient gas flow, the tip will overheat. As the tip becomes overheated, it will begin

Figure 25-49 (a) When first lit, low-pressure acetylene has smoke; (b) increase acetylene pressure until smoke disappears; (c) turn on oxygen and slowly increase flow; (d) increase oxygen until the outer feather forms into a very smooth uniform cone; (e) excessive oxygen causes the flame to become purple, and the inner cone becomes very small.

to pop. This popping is called a backfire, and backfires can result in damage to the equipment. A backfire can result in a flashback, where flame actually races back through the hoses to the cylinders. If this were to occur, the results could be catastrophic: the system could explode. Flashback arrestors and check valves can be installed on the torch handles to guard against both flashback and reverse flow (Figure 25-50). Incorrect shutoff can also cause the torch to

backfire. To safely shut off an oxyacetylene torch and avoid a backfire, close the oxygen valve on the torch handle first and then close the acetylene valve (Figure 25-51).

Putting up the Torch

When you are finished with the torch, close the cylinder valves and release the pressure from the hoses and regulators. Bleed

Figure 25-50 Flashback arrestors and check valves can prevent dangerous reverse-flow conditions.

Figure 25-51 Close the oxygen valve first and the acetylene valve last.

the acetylene first and then the oxygen. The acetylene and oxygen should be bled individually, one at a time, to avoid creating a flammable mixture. Once the pressure has been relieved from both the oxygen and acetylene hoses and regulators, back out or loosen the regulator-adjusting valve handle. Make certain you do not over-loosen the valve handle, as in some cases it can completely unscrew and fall out of the regulator body. If this does occur, be very careful not to cross-thread the adjusting handle as you reinstall it. Many manufacturers use nylon threads in the regulator so that oil is never needed for them to operate smoothly. The nylon is easily cross-threaded.

SERVICE TIP

From time to time the oxyacetylene tip becomes dirty. To clean the tip, use a tip cleaner of the proper size and clean out the dirt that has collected in the tip orifice (Figure 25-52). Select a tip cleaner size that will easily fit into the hole in the tip. Tip cleaners are actually small, round files that are accurately calibrated for each tip size. By sliding the tip cleaner in and out several times, you will remove the debris inside the tip, as demonstrated by Figure 25-53.

25.9 BRAZING

Brazing and soldering are similar processes. The primary difference is that soldering occurs below 840°F and brazing occurs above 840°F. Most manufacturers and codes require that refrigerant line joints be made using brazing alloys. Oxyacetylene torches are preferred for brazing because they can quickly heat up joints to brazing temperatures. The faster a joint is heated, the fewer surface oxides are formed. Heating the joint quickly also lowers the chance that heat will be conducted from the joint to damage surrounding parts. Overheating can damage many refrigerant system valves. The longer that copper is kept at the higher brazing temperature, the greater the formation of copper oxide (Figure 25-54). Copper oxide can become a barrier to the successful completion of the joint as well as becoming a contaminant in the refrigerant circuit.

Figure 25-53 Use the round tip cleaner to clean the tip orifice.

Brazing Alloys

Brazing alloys used in HVACR fall into two general categories: copper phosphorus and high-silver-content brazing alloys. Copper-phosphorous alloys typically contain copper, phosphorous, and silver. Copper-phosphorous brazing alloys are typically supplied in flat rods with silver percentages from 0 to 15 percent (Figure 25-55). Copper phosphorous rods are only used for brazing copper to copper joints (Figure 25-56). They do not work on ferrous metals like iron and steel and are usually not recommended for brass. Copper-phosphorous alloys do not require flux; the phosphorous acts as the flux. The phosphorous cleans off the copper oxide deposits at the relatively high temperatures that copper-phosphorous flows (1,200°F – 1,600°F). Copper-phosphorous rods are the most commonly used brazing material in HVACR.

Figure 25-55 Copper-phosphorous brazing rods.

Figure 25-56 Copper-phosphorous rods are only used for copper-to-copper joints.

Figure 25-57 High-silver-content silver brazing material was used to braze this copper line to this steel shell.

High-silver-content silver brazing alloys are used for connecting copper lines to brass and steel fittings (Figure 25-57). High-silver-content brazing alloys contain 35–56 percent silver. Most high-silver-content brazing alloys are sold by the troy ounce in spools (Figure 25-58). High-silver-content brazing materials work with copper, ferrous materials such as iron or steel, and brass. They do require cleaning and fluxing with silver brazing flux (Figure 25-59). Some silver brazing rods have flux already applied to the outside of the rod (Figure 25-60). Because of their high cost, high-silver-content brazing rods are normally only used for joining different type of metals.

Preparing a Brazed Joint

To make a proper brazed joint in copper, the copper fittings must be clean. Clean new fittings might only need to be

wiped off, but pipe and fittings that have been discolored from oxide must be cleaned mechanically or chemically. Mechanical cleaning is easiest performed using sand cloth (Figure 25-61) or a wire brush (Figure 25-62). Specially designed round wire brushes fit inside of copper fittings to provide better cleaning. These round brushes or small flat brushes can also be used for cleaning the outside of the pipe. Sand cloth or abrasive pads for cleaning copper pipe and fittings are available. Sand cloth should not be confused with emery cloth. Emery cloth is a very hard, abrasive material, and any abrasive grit, if left inside the pipe, can damage a piston or other moving parts. AC-type sand cloth has softer grit that will more easily break down if the grit is accidentally left in the system, reducing the possibility of damage to moving parts.

The pipe should be cleaned at least $\frac{1}{2}$ in farther back than the pipe fits into the fitting, shown in the series of photos in Figure 25-22. Because copper oxidizes in the air, it is best to clean the fittings immediately prior to producing the brazed joint. Do not touch the cleaned surfaces with your hands or oily tools. The oil can contaminate the cleaned surfaces and keep the brazing material from sticking.

Figure 25-61 (a) Use aluminum oxide sand cloth to clean copper before brazing and soldering; (b) be sure to clean all the way around the fitting.

Figure 25-62 Round tubing brushes can be used to clean the inside of pipe and fittings.

SERVICE TIP

Push the cleaned copper pipe as deeply as possible into the copper fitting (Figure 25-63). Twisting the pipe once it is completely inserted can help seat it completely to the bottom stop of the joint (Figure 25-63). On fittings that have a stop all the way around the inside or on swaged fittings, this can prevent braze or solder from flowing into the pipe.

Figure 25-63 (a) Insert the copper pipe into the fitting; (b) twisting the copper pipe against the stop helps seat the fitting.

Heating the Copper Pipe

The order in which you heat the parts is crucial to a quality brazed joint. It is important to heat the pipe first (Figure 25-64a) and then the fitting (Figure 25-64b). As the copper pipe is heated, it will expand. This expansion will tighten the joint space between the fitting and the copper pipe. If the fitting were to be heated first, this space would increase. The tighter the space is, the better

Figure 25-64 (a) Begin heating the pipe near the fitting; (b) once the pipe is hot, move the flame onto the fitting and continue heating.

Figure 25-65 Once brazing temperatures have been reached, use a slight downward pressure on the filler rod at the braze joint and follow the joint around the fitting.

the heat transfer and the greater the capillary attraction for the liquid braze metal. The capillary attraction is the force that draws molten braze metal deep into the joint.

Once the pipe has become hot, approaching a dull red color, move the torch flame onto the fitting so that it envelops both the fitting and the pipe (Figure 25-64b). Continue heating the fitting. Occasionally touch the pipe surface with the tip of the brazing rod as a test of temperature readiness. A small drop of braze material may transfer from the rod to the fitting just before the fitting reaches brazing temperature.

One big difference between soldering and brazing is that you must continue to heat the braze joint even after the braze material starts to flow. (Figure 25-65). You must slowly move the flame while heating to avoid burning through the copper. When the copper gets “cherry red,” the copper is very near its melting point of 1,984°F. Some copper-phosphorous brazing alloys do not flow well until the copper is almost cherry red. The temperature of the oxyacetylene torch coupled with the higher pressure of the oxyacetylene flame makes burning holes in the copper very easy. To avoid this, the torch should be in constant motion to avoid concentrating the heat and pressure on any one spot. Move the flame between the pipe and fitting in a concentric circle, always pointing the flame in toward the center of the pipe. Avoid moving the flame side to side and “fanning” the flame. This increases the time required to heat the joint and increases oxide formation.

A slight pressure on the filler metal into the joint will aid in forcing the filler metal more deeply into the joint space (Figure 25-66). It is important that the filler metal flow completely to the base of the joint. Any unfilled gaps can result in joint failure, especially when R-410A refrigerants are being used. These higher-pressure refrigerants will cause the copper pipe to expand slightly as the pres-

Figure 25-66 Add the filler metal straight into the joint gap.

sure inside the pipe increases. If the pressure decreases, the pipe will contract. This cyclical expansion can cause a stress fracture if the joint is not completely filled with brazed metal. If you watch carefully, you can see a slight change in the fitting’s color as the filler metal flows into the joint space. This change in color is more obvious for larger-diameter fittings. Bringing the torch down on the fitting will help draw the filler metal completely into the joint.

Once the joint gap has been filled, move the torch back up above the joint and add a small amount of braze metal until a fillet of metal surrounds the joint (Figure 25-67). This fillet serves two purposes. First, the fillet makes it easier to visually check the joint to see that it has no leaks. Second, it removes any sharp transition between the two pieces of copper, the fitting and the pipe, which will further reduce stress cracking when high-pressure refrigerants (e.g., R-410A) are being used.

Cleaning the Brazed Joint

Some fluxes are neutral at room temperature and only become active when heated to a specific temperature. Other fluxes are active irrespective of the temperature. All fluxes must be removed from the completed joint. This is particularly true for active fluxes. If flux is allowed to remain on the joint it can cause corrosion. Flux can trap moisture, causing pitted corrosion, or it may obscure small pinhole leaks,

Figure 25-67 Add a small amount of braze to the joint so that there is a smooth, uniform fillet to ensure a good joint seal.

Figure 25-68 This horizontal refrigerant line is 1 in above the ground, making access to the bottom of the joint difficult.

which could open later, causing system leaks. Active fluxes can significantly damage metal parts if not completely cleaned away and neutralized.

Horizontal Brazed Joint

Horizontal brazed joints are the most common joints experienced in the HVAC field. Horizontal joints are typically found at the junction of the refrigerant line set and the outdoor unit as well as from the refrigerant line set to the evaporative coil. When practicing this joint, it will be beneficial to you later if you will work from just the top side of the joint. Because these joints are typically close to the ground in most installations, you cannot see the bottom of this joint when making it in the field, such as the joint shown in Figure 25-68. Using the torch, heat the filler metal approximately 2 in from the end. When the rod becomes soft, bend it to approximately a 90° angle (Figure 25-69). This will allow you to direct the filler metal into the bottom portion of the joint while your hand and torch are working from above. Again, always heat the copper pipe first. Then move your torch to the fitting. When the pipe and fitting are hot enough, as indicated by the red color shown in Figure 25-64, add filler metal directly into the groove space (Figure 25-70).

Sometime while you are brazing, you might accidentally touch the tip of the filler metal to the joint. If it becomes stuck, simply move the torch flame over until the rod melts itself free. Watch the filler metal, and do not overfill the joint. Overfilling will result in a drip of brazed metal hanging from the bottom of the joint. When the joint has been completely filled, simply wipe the tip of the brazed metal

Figure 25-69 Use the flame to heat and bend the brazing rod approximately 2 in from the end to make reaching the bottom of the horizontal joint easier.

Figure 25-70 When the fitting is completely heated, filler metal can be added from the bottom first; then follow the joint around with the tip of the filler metal ending at the top of the joint.

rod across the bottom joint. This will provide a slight fillet around the joint. On larger-diameter copper pipe and fittings (1 in or larger), it is usually necessary for you to move the torch around so that the flame is directed on the bottom surface. As you move the torch around, pay particular attention so that you do not inadvertently direct the flame toward yourself, others, or combustible materials in your work area. Learning to be aware of the flame direction will help you in the field to avoid burning the paint off of equipment as braze joints are performed.

Vertical Up Joint

Occasionally in the field, a brazed joint must be made in the vertical position with the joint on top. The filler metal

must travel uphill to fill the joint. These joints are typically found, for example, when a 90° fitting or coupling is joined in refrigerant line sets. Start by heating the copper pipe just as with the other brazing practices. When the pipe is properly heated, move the torch up on the fitting so that the flame covers both the joint and pipe. Continue heating the copper pipe and fitting until the brazed metal begins to flow. Using a slight inward pressure, hold the tip of the filler metal against the joint and press upward. This slight pressure along with the heat and capillary space will draw the filler metal deeply into the joint (Figure 25-71). When the joint has been completely filled, wipe the tip of the filler metal around the joint groove to produce a soft fillet of brazed metal. It is important not to overfill this joint, as this will result in a drip of brazed metal hanging down on the pipe.

Testing Brazed Joints

In the field, evacuating and charging the system places the brazed joints under both vacuum and pressure conditions.

Figure 25-71 Inward pressure of the filler metal helps in filling the joint gap completely with brazes in the vertical position.

Figure 25-72 The first step in braze joint testing is to cut the fitting just beyond where the pipe is seated.

This will serve the purpose of testing the brazed joints. In the refrigeration and air-conditioning lab, you can test the brazed joints in a different manner. It is possible to inspect your brazing by destructively testing the joint. To perform this destructive test, first use a hacksaw to saw off the copper and copper fitting at a point just beyond the depth that the pipe was inserted into the joint (Figure 25-72). Once the fitting has been cut completely apart, clamp the pipe in a vise and cut straight down through the entire joint into the pipe. Rotate the pipe 90° and repeat this process, cutting as shown in the diagram in Figure 25-73. First bend each quarter out with a wrench (Figure 25-74a). Using a hammer and anvil, flatten each of the four corners of the pipe and fittings you just made (Figure 25-74b). As the joint pieces are flattened, it is easy to see areas where 100-percent joint penetration did not occur (Figure 25-75). Repeat the practice until you can successfully pass each of the four various joints without finding voids during testing. Obviously, this test will render the joint unusable. The technician may use this test for the practice and development of brazing skills.

TECH TIP

The stubs on new hermetic compressors and filter driers look like copper. Often, the copper is actually a very thin coating on a steel pipe. The copper coating is put on the stubs to aid in brazing the refrigerant lines to the compressor. This thin copper coating is easily damaged by overheating if the oxyacetylene torch flame is an oxidizing flame or if too much time is taken during brazing. To keep from burning off the copper coating, be sure to use a neutral oxyacetylene flame, and use a torch tip that is big enough to do the job quickly. If the copper coating is damaged, you will have to stop, disassemble the joint, and clean it before restarting. In that case, it will also be necessary to use a silver brazing filler and a brazing flux.

Figure 25-73 Use a hacksaw to make two cuts through the entire length of the fitting.

25.10 NITROGEN BRAZING

Brazing creates metal oxides on all the parts being brazed, both inside and outside the pipes (Figure 25-76). The oxides can come loose and contaminate refrigeration systems. Oxides are formed by a chemical reaction between oxygen and a metal. If there is no oxygen, the oxides cannot form. Refrigeration lines should be purged with nitrogen during brazing to prevent the formation of copper oxides inside the pipe. The nitrogen replaces the air, eliminating the oxygen and preventing the formation of oxides. Figure 25-77 shows a piece of copper after heating while being purged

with nitrogen. Notice that it is oxidized on the outside and clean on the inside.

Nitrogen Cylinder Safety

Nitrogen is inherently safe. It does not burn, it does not chemically react with many substances, and it is not poisonous. We breathe nitrogen all the time, as air is 78 percent nitrogen. However, nitrogen can be dangerous because it does not irritate our lungs or eyes. You will not have any warning that the closed area you are in is so full of nitrogen that there is no longer enough oxygen. You will just

get dizzy, pass out, and asphyxiate. To avoid asphyxiation, never release large quantities of nitrogen inside a closed space. Nitrogen cylinders can be dangerous because of the very high pressures inside them. They typically have over 2,000 psig of pressure when the cylinder is new. This much pressure on a refrigeration system would cause parts to rupture and explode. You should always use a pressure

regulator and a pressure-relief valve when using nitrogen. Figure 25-78 shows a nitrogen regulator with a built-in pressure-relief valve. The pressure regulator lets you safely control the pressure you put into the system. The pressure-relief valve keeps the downstream pressure from reaching full tank pressure should the regulator fail. Most refrigera-

tion systems have system design pressures on their data plates (Figure 25-79). These are not the operating pressures but the maximum pressures the system is designed to withstand. You should never exceed the system's design pressure when field testing a system. It can be difficult to ensure that the high side and low side of an installed system will remain segregated, so the safest procedure is to never exceed the low-side design pressure. If the system does not list a design pressure, use 150 psig as the maximum safe test pressure. Hermetic compressor manufacturers list 150 psig as the maximum safe test pressure on the hermetic compressor shell. Normally you should not use pressures anywhere close to system design pressure when nitrogen purging.

Opening the Nitrogen Cylinder

The nitrogen cylinder should be treated with care. To open the nitrogen cylinder, stand behind the cylinder on the side opposite the regulator so that you are not in a direct line with the regulator and slowly crack open the valve counterclockwise. Once you see a reading on the pressure gauge, open the cylinder valve all the way counterclockwise.

SERVICE TIP

Nitrogen brazing is especially important on systems that use HFC refrigerants with polyol ester (POE) lubricant, such as today's new R-410A air-conditioning systems. POE and HFCs are very strong solvents and "clean" the oxides off of the inside of the copper lines. The oxides then end up in the compressor oil and in metering devices, causing major system failures.

Purging Procedure

You cannot braze a system that is pressurized, as the pressure will simply blow a hole in the molten braze material. The nitrogen must be able to leave the system so that pressure does not build up. Introduce nitrogen at one point in the system and release it at another point. Remove the cores from Schrader valves to improve flow and insure the release of the nitrogen (Figure 25-80).

Begin by purging with enough pressure to purge all the existing air from the lines. Adjust the regulator in

clockwise until you have a pressure of 50 psig and purge for one minute. This will safely clear most lines (Figure 25-81). The pressure and flow must be reduced before brazing. Turn the regulator out counterclockwise until there is a slight flow of nitrogen leaving the open valve on the system. It should feel similar to blowing on the back of your hand. This pressure is under 2 psig and will not show on most nitrogen gauges (Figure 25-82). Brazing proceeds just as it would normally, except now there will not be any oxides formed inside the lines. Leave the nitrogen flowing after completing the brazing until the lines are cool.

UNIT 25—SUMMARY

Soldering, brazing, and welding are all methods of joining metal parts using molten metal. During welding, the base metal itself is melted as additional metal filler is added to the joint. During soldering and brazing, only the metal being added to join the base parts is melted. The difference between brazing and soldering is temperature. Soldering takes place below 840°F and brazing takes place above 840°F. Three types of torches used for soldering and brazing are air fuel, swirl-tip air fuel, and oxyacetylene. Air-fuel and swirl-tip air-fuel torches get their oxygen from the air. Oxyacetylene torches use pure oxygen supplied by a highly pressurized oxygen cylinder. Air-fuel torches are mainly used for soldering. Swirl-tip torches get hot enough to braze and do not require a separate oxygen cylinder. Oxyacetylene torches are the hottest burning torches and are preferred for brazing. Oxygen cylinders should always have their safety cap on when being transported. Acetylene cylinders safely store acetylene at high pressures by dissolving it in acetone, which is held inside the cylinder with a sponge-like filler material. Acetylene is unstable and can explode at pressures above 15 psig. It should never be used at pressures above 15 psig.

The first step in soldering and brazing is to clean the joint. Filler alloy will not stick to dirty, oxidized metal. When heating the joint, heat the pipe first and then move to the fitting. The torch should heat the metal and the metal should melt the solder or brazing alloy. Oxidation is created when metal is brazed. This can be avoided by purging the lines with nitrogen during the brazing process.

Refrigerant System Piping

OBJECTIVES

After completing this unit, you will be able to:

1. explain the importance of minimizing pressure drop through the lines.
2. explain the importance of maintaining minimum gas velocities in the lines.
3. calculate the pressure drop in a liquid line due to vertical lift.
4. list the system modifications required for long-line applications of residential air-conditioning systems.
5. list some of the differences between air-conditioning and commercial refrigeration piping.
6. size refrigeration lines using line sizing charts.

26.1 INTRODUCTION

How does a technician determine what size lines to run when installing a refrigeration system? One common method is to measure the fittings where the refrigerant lines connect on the unit and use that size. If installations are restricted to “standard” installations, this method will often work. However, there are many variables that affect the size of refrigerant lines that cannot be determined without knowing the details of a particular installation. The penalty for incorrectly sizing the refrigerant lines can range from poor system performance to multiple compressor failures. It is in your best interest to know how to size refrigerant lines correctly. Refrigerant line sizing can be important from a service standpoint also, since it affects system performance. Understanding line-sizing concepts will help you solve those elusive problems that other mechanics cannot.

26.2 GOOD REFRIGERANT PIPING PRACTICES

There are good piping practices that should be followed when sizing and installing a refrigerant piping system:

- Keep it clean. Cleanliness is a key factor in the actual installation. Dirt, metal filings, sludge, and moisture will cause breakdown in the system and must be avoided. Neat, clean work will avoid many service difficulties.
- Pressure drop through all sections of piping should be kept to an absolute minimum to maximize system capacity and efficiency. Use as few fittings as possible. Fewer fittings mean less chance for leaks and, more important, less needless pressure drop.
- Each section of the piping system must also be sized to ensure enough velocity for proper oil

return. In those installations where oil return and pressure drop are in conflict, proper oil return takes precedence.

- Be careful in making every connection. Use the right material and follow the method recommended by the equipment manufacturer. The lines should be purged with nitrogen during brazing to eliminate the formation of copper oxide inside the lines.
- Pitch horizontal lines in the direction of refrigerant flow (Figure 26-1). To aid in forcing oil to travel through lines that contain vapor (suction line, hot-gas line), horizontal lines should be pitched in the direction of refrigerant flow. To help the oil flow in the right direction, this pitch should be a minimum of $\frac{1}{2}$ in for each 10 ft of run. Pitch also helps to prevent back-flow of the oil during shutdown. In piping systems where sufficient return-gas velocity can be ensured at all times, it is satisfactory to run the horizontal suction lines dead level. This may be desirable where headroom is at a premium or where a sloping run will interfere with other piping.

Figure 26-1 Lines should be sloped at least $\frac{1}{2}$ in per 10 ft of run in the direction of refrigerant flow.

TECH TIP

Selecting the correct refrigerant lines can be very complex, involving many factors. One factor, however, that should be considered the least is the cost of the materials. Copper line sets are frequently undersized for cost savings. However, undersizing a system's refrigerant lines significantly reduces the system's performance. Reduced performance means extended operation and higher operating costs. The money saved on the initial installation is quickly spent on power bills.

26.3 REFRIGERATION LINE SIZING PRINCIPLES

Figure 26-2 shows a typical refrigeration piping system. The piping that connects the four major components of the system has two major functions: it provides a passageway for the circulation of refrigerant, and it provides a passageway through which lubricating oil carried out with the refrigerant is returned to the compressor. Each section of the piping should fulfill these two requirements with a minimum pressure drop of the refrigerant. Excessive flow resistance will increase pressure drop through the refrigerant piping and reduce the system's efficiency. A pressure drop in the refrigerant lines kills the system capacity and increases operating costs. In general, the larger and straighter the line, the less pressure drop it will have.

However, excessively large piping causes low refrigerant flow velocity, which reduces the amount of oil return-

ing to the compressor. The best way to keep refrigerant velocity up is to make the lines smaller. So piping that is too small causes loss of efficiency, and piping that is too large can prevent refrigerant oil from being returned to the compressor.

26.4 ALLOWABLE PRESSURE DROP

It is desirable to minimize the pressure drop when sizing refrigerant lines. If the lines are too small, the capacity of the equipment is reduced. Standard practice has been to design gas lines for a maximum pressure drop roughly equal to a 2°F drop in saturation temperature. The actual amount of pressure drop this represents depends upon both the type of refrigerant and the temperature of the refrigerant. The acceptable pressure drop in the discharge line is almost twice as much as in the suction line. Systems using R-410a can have a higher pressure drop in the lines than systems using R-134a.

To see how this works, let's examine two systems operating at an evaporator saturation temperature of 40°F: one using R-134a and the other using R-410a. For R-134a, the saturation pressure at 40°F is 35 psig and the saturation pressure of 38°F is 33 psig. So the R-134a system can have a maximum pressure drop in the suction line of 2 psig (Figure 26-3). In the R-410a system, the saturation pressure at 40°F is 118 psig and the saturation pressure at 38°F is 114 psig (Figure 26-3). The R-410a system can have a 4-psig pressure drop for the same 2°F saturation temperature drop. The R-410a system can operate at twice the suction line pressure drop as the R-134a system and still operate efficiently.

Temperature °F	R-134a	R-410a
36°F	31.3	109.9
38°F	33.1	114.3
40°F	35.0	118.8
42°F	37.0	123.4

Figure 26-3 Comparison of pressures for R-134a and R-410a.

TECH TIP

An ideal refrigerant piping system has a pressure differential equivalent to less than 2°F temperature difference between the indoor coil and the outdoor unit. Refrigerant pressures and temperatures are not linear. There is more temperature difference associated with each pound of pressure change at lower temperatures than at higher temperatures. Suction lines for refrigeration applications must be sized for less pressure drop than air-conditioning systems because air-conditioning systems operate at higher evaporator temperatures. Refer to the pressure-temperature chart and the operating temperature range of the system you are working on to determine what pressure difference is related to a 2°F temperature drop at the system's normal operating temperature.

TECH TIP

As the suction pressure drops, it has a greater effect on the compressor's compression ratio. The compression ratio is the absolute suction pressure divided into the absolute discharge pressure. If the suction pressure drops as a result of undersized refrigerant piping, the compression ratio will go up significantly. Compressor discharge temperatures will rise as a result of increased compression ratio, leading to oil breakdown, acid formation, and eventual compressor failure.

26.5 IMPORTANCE OF OIL RETURN

In an ideal system, all the compressor oil would stay in the compressor. However, the compressor surfaces that are moving the refrigerant are lubricated with oil and a small amount of oil is swept out of the compressor with the discharged refrigerant. This results in the unavoidable loss of oil from the compressor. Returning oil to the compressor is crucial for the health of the system. The compressor will eventually be destroyed by lack of oil return if the piping system does not adequately return the compressor oil.

In reciprocating compressors, some of the oil in the crankcase gets on the cylinder walls during the downstroke of the piston and is blown out with the compressed vapor refrigerant through the discharge valve on the compression stroke (Figure 26-4).

Figure 26-4 Some oil leaves the compressor with the refrigerant.

Some compressors lose much less oil than others, but there is no way to design a compressor that does not lose any oil into the refrigerant piping. This oil serves no other useful purpose in the system except to lubricate the compressor.

The presence of oil in the evaporator and condenser coils can reduce the capacity of the heat-exchange surfaces as much as 20 percent, because the excess oil forms an insulating coating on the interior surfaces of the refrigerant tubes. This, in turn, can cause thermal expansion valves (TEVs) to feed excess amounts of liquid refrigerant. Therefore, the presence of oil in the piping must be taken into consideration when installing piping. A piping system that is not correctly constructed to allow oil return can cause the following problems:

- Seized compressor bearings due to insufficient oil returning to the compressor for lubrication.
- Broken compressor valves, valve plates, pistons, and/or connecting rods due to liquid refrigerant and/or large quantities (slugs) of oil entering the compressor. It is important to understand that the compressor is designed to pump vapor and will not pump liquid.
- Loss of capacity caused by the oil occupying portions of the evaporator, thus reducing the amount of effective surface and the overall system capacity.

26.6 GAS VELOCITY

Oil return in refrigerant piping is accomplished by refrigerant gas velocity. The refrigerant must move fast enough through the lines to carry the oil droplets with it. The minimum required velocity actually varies depending upon the type of refrigerant, the temperature of the refrigerant, and the size of the refrigerant line. In general, large lines require a higher velocity for oil return than smaller lines do. Figure 26-5 shows minimum recommended velocities for oil return based on factors like refrigerant type, evaporator temperature, direction, and line size. Notice that the larger lines require higher velocities than smaller lines.

Figure 26-5 Minimum recommended velocities for oil return (feet per minute, FPM).

Also, lower-temperature lines require higher velocities than higher-temperature lines.

Frequently the complexity of minimum refrigerant line velocity is simplified by quoting a single figure for horizontal velocity and another for vertical line velocity. A safe range of velocities for most applications is 500–750 feet per minute (FPM) for horizontal lines and 1,000–1,500 FPM for risers. Typically the minimum required velocity for a vertical riser is twice the velocity for a similar horizontal section of piping. A quick look at Figure 26-5 shows that velocities considerably less than these can work, depending upon the variables listed in the table. However, it does not hurt for the velocity to be faster than the absolute minimum as long as it does not become excessive. The maximum gas velocity should be kept under 3,000–4,000 FPM to minimize noise. Normally, line sizes that would yield gas velocities in excess of 3,000 FPM would create too high a pressure drop to be acceptable anyway.

26.7 HOT-GAS LINE

In sizing and arranging hot-gas lines, select tubing with a diameter small enough to provide the velocity to carry the hot vaporized oil to the condenser. On the other hand, the diameter must be large enough to prevent excessive pressure drop. In hot-gas lines, a pressure drop equivalent to a 2°F saturated temperature drop is recommended, but a greater loss can be accommodated if conditions demand it.

If a discharge line has excessive pressure drop, the velocity of gas flow through the line can be excessive, causing noise, vibration, and serious reduction in system capacity. There would also be an increase in operating cost due to the higher compressor discharge pressure required.

The velocity needed to move oil up long discharge risers sometimes creates an unacceptable pressure drop. The installation of an oil separator, such as shown in Figure 26-6, is an alternative to moving oil up the discharge riser. The oil

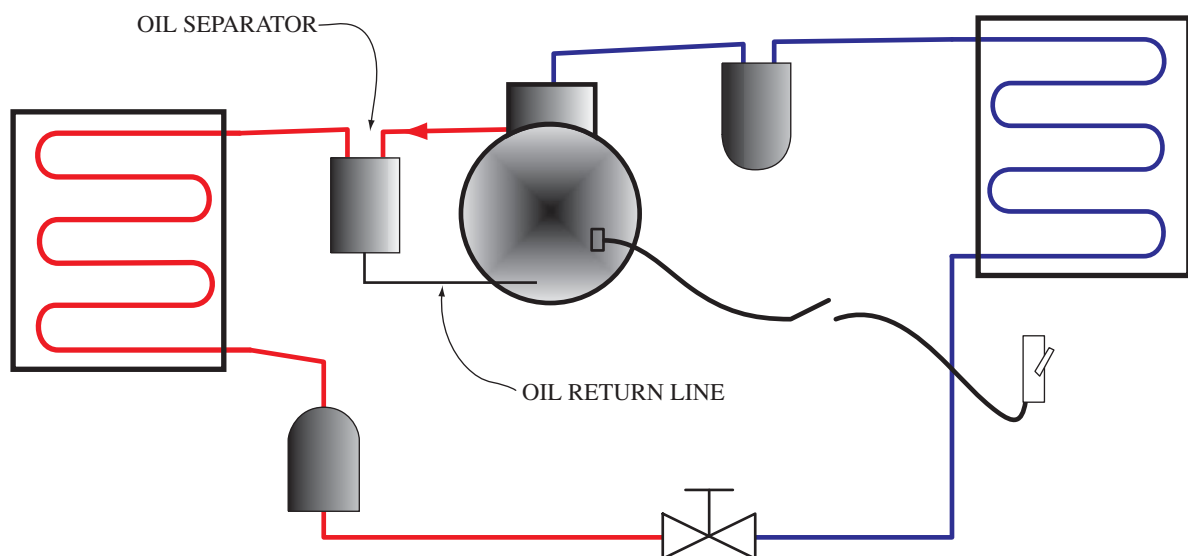

Figure 26-6 Discharge piping with oil separator.

Figure 26-7 The condensate line should be large enough to allow free drainage of liquid from the condenser to the receiver.

from the separator is usually returned to the crankcase of the compressor. With this arrangement, the hot-gas riser can be sized for a lower pressure drop.

26.8 CONDENSER CONDENSATE LINE

The line between a condenser and a liquid receiver is called the condensate line. The objective in sizing condensate lines is to provide ample size, allowing free drainage of the liquid refrigerant to the receiver while the gas refrigerant flows over the liquid in the opposite direction, thus serving as an equalizer line as well as a liquid drain (Figure 26-7). It is almost impossible to oversize the condensate line; 0 psig pressure drop is desirable. Undersizing or installing too long a line should be avoided. An undersized or excessively long line can restrict the flow of refrigerant to the receiver to the extent that some refrigerant will be held back in the condenser. The effective condenser surface is reduced when the condenser begins to fill with liquid, reducing condenser capacity. This causes the head pressure to rise, decreasing the overall system capacity. At the same time, power requirements and operating costs increase.

For proper operation, the length of the line between the condenser and receiver must be kept as short as possible. The top of the receiver should be level with, or preferably below, the bottom of the condenser. This eliminates the need for the liquid to be forced uphill to enter the receiver. The condenser drain line is not usually insulated.

26.9 LIQUID LINE

Liquid lines do not present a problem from an oil-return standpoint because liquid refrigerant and oil mix easily and the oil is carried through the liquid line with ease. Liquid lines, however, are critical for pressure loss both from a pressure drop due to pipe size and, in the case of the vertical upflow line, vertical lift of the refrigerant. Liquid

lines are sized for a pressure drop equivalent to a 2°F saturation temperature drop. The pressure drop through the liquid line can be increased if enough subcooling is added to offset the pressure drop. The subcooling should be at least 1°F more than the equivalent saturation temperature drop. If the pressure drop through the liquid line will cause a saturation temperature drop of 4°F, the liquid must be subcooled at least 5°F to prevent flash gas.

Long, large-diameter liquid lines can add a considerable amount of charge to the system. Figure 26-8 shows the amount of refrigerant contained in each foot of liquid line for different diameters of tubing. Line lengths that cause the system charge to exceed the maximum charge limit of the compressor should be avoided. To limit the amount of refrigerant in the system, most residential air-conditioning system manufacturers use 3/8-in liquid lines for split systems using remote condensing units. However, the size of the liquid line will vary with tonnage and line length on commercial systems. Do not change the liquid line size from the original specifications because incorrectly sized liquid lines can seriously reduce system capacity and reduce the equipment life.

Figure 26-8 Amount of refrigerant charge per foot of line.

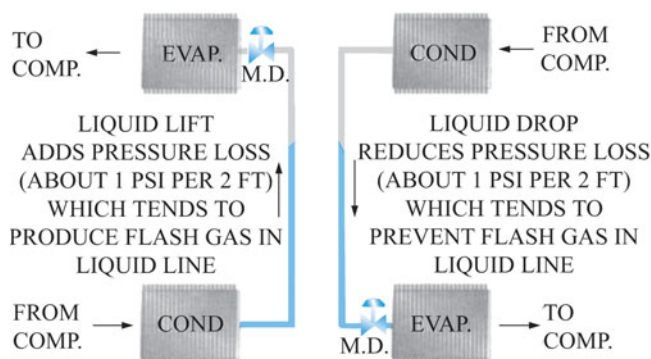

Figure 26-11 Liquid line static head with lift or drop conditions.

Standing columns of liquid exert a force on the bottom of the column due to their weight. Refrigerants are no different. For example, a standing column of liquid R-22 at 100°F and 210 psig exerts a pressure of approximately 0.50 psi for every foot of height of the column due to its weight. R-410A exerts 0.43 psi/ft of height. The pressure at the bottom of a 10-ft column of R-22 is 5 psi greater than the pressure at the top of the column. Conversely, for every 10 ft that R-22 is lifted in a vertical riser, the pressure at the top of the column is reduced by 5 psi. Figure 26-11 shows the effect of vertical lift in liquid lines.

Take the case of an R-22 system with a 30-ft lift, a 6 psi pressure drop in the liquid line, a condensing temperature of 105°F, and 3°F of subcooling. Considering the 3°F of subcooling, the liquid leaves the condenser at 102°F, 211 psig. If the liquid line riser has a 30-ft lift, the pressure at the top of the riser would be 15 psi less due to the weight of the refrigerant. The final pressure would be:

$$\begin{aligned} 211 \text{ psig} - 15 \text{ psig} &= 196 \text{ psig} \\ 196 \text{ psig} - 6 \text{ psig line loss} &= 190 \text{ psig} \end{aligned}$$

This will produce a boiling point of 98°F. Since the liquid left the condenser at 102°F, enough liquid will vaporize to cool the remaining liquid to 98°F. To avoid the formation of flash gas in this riser, liquid subcooling leaving the condenser of 8°F or more is required to compensate for lift and pressure drop in the line. This can be accomplished by the use of a liquid-to-suction-line heat exchanger.

Again, assume that the same conditions are applied to an air-conditioning unit with 15°F of subcooling. The pressure loss in the liquid line could be much greater before flash gas is formed. Instead of leaving the condenser at 102°F as it did with only 8°F of subcooling, the liquid would leave at 90°F. The saturation pressure for 90°F R-22 is 168 psig. The pressure loss due to vertical lift could be as high as $211 - 6 - 168 = 37$ psi. The vertical lift could increase to 74 ft before flash gas would occur ($74 \times 0.5 = 37$).

This demonstrates the value of a proper amount of subcooling. It not only provides latitude for the designer when laying out the liquid line, but the proper amount of subcooling provides the maximum system capacity at the lowest operating cost.

This also highlights the importance of avoiding vertical lifts in the liquid line. Where possible, avoid installations with large vertical distances between the condensing unit

and the evaporator. An example of a problematic installation would be a condensing unit on grade and the air handler in the attic of a multistory dwelling. Flash gas, reduced capacity, and increased operating cost are all likely to be problems.

If you cannot avoid this situation, provide enough liquid subcooling to overcome the pressure loss. Extra subcooling can be obtained by using a suction-to-liquid heat exchanger or stacking the liquid and suction lines together and insulating both lines inside a common wrap to promote heat exchange from the liquid to the suction line.

26.12 SUCTION LINE

Oil circulates throughout the system and must be returned to the compressor to prevent damage to the compressor. The most critical line in performing this function is the suction line. For example, observe the behavior of two common refrigerants used in refrigeration and air conditioning, R-22 and R-410A. In liquid form, these refrigerants will mix with oil and carry it along the piping with ease. Therefore, few, if any, oil problems exist in the liquid line. However, in their gaseous state, the refrigerants are poor carriers of oil.

Oil in the suction line is at a lower temperature than the rest of the system and therefore has higher viscosity, which slows down the flow over pipe surfaces. Also, the refrigerant is in vapor form and has only a mechanical effect on the oil. The vapor does not absorb the oil.

Minimum suction gas velocity is normally between 500–750 FPM for horizontal runs and 1,000–1,500 FPM for vertical runs. This is the minimum velocity needed to bring back the oil to the compressor. If there is a conflict between the size needed to achieve the minimum velocity required for oil return and the size needed to achieve a low-pressure drop, size the suction line to achieve the minimum velocity for oil return. Be sure to check the velocity and size of both the horizontal and vertical sections of pipe, since the minimum velocity for a vertical rise is greater than for a horizontal run. Frequently the best size for the horizontal run will be larger than the best size for the vertical riser (Figure 26-12). It is good practice in these cases to make the vertical piping smaller than the horizontal piping. This keeps pressure drop to a minimum and still maintains the

Figure 26-12 Reduced-size suction gas pipe riser.

minimum required velocity for oil return. The suction line, therefore, must be carefully designed to ensure a uniform return of dry refrigerant gas as well as sufficient oil to the compressor.

The maximum recommended saturation temperature drop in the suction line is 2°F. The equivalent pressure drop is different for different refrigerants. The suction pressure drop is important because it has a great effect on the compressor compression ratio. Reducing the suction pressure to the compressor increases the compression ratio. Any increase in this ratio reduces the capacity of the compressor to pump refrigerant vapor and increases the power required.

For example, for R-22 at 0°F, a 10°F temperature drop produces a 7-psi pressure drop from 23.9 psig at 0°F to 16.5 psig at -10°F. With a 195.9 psig, 100°F saturation condenser, the compression ratio at 0°F is calculated as

$$(195.9 + 14.7)/(23.9 + 14.7) = 5.45$$

With a -10°F evaporator the compression ratio becomes

$$(195.9 + 14.7)/(16.5 + 14.7) = 6.75$$

26.13 EQUIVALENT LENGTH OF FITTINGS

There is some pressure loss through every fitting and device in the refrigeration line. This pressure loss must be taken into account when sizing lines. The most common way of accounting for the pressure loss through fittings and devices in refrigeration lines is to compare the loss through each fitting as equivalent to the loss through a length of pipe. Tables give the equivalent length for different sizes and types of fittings. Figure 26-13 gives the equivalent length for common fittings and valves. Note that the equivalent length increases as the pipe size increases.

When looking up line lengths in sizing tables, the length that should be used is the line's total equivalent length. The total equivalent length is the sum of the line's actual length plus the equivalent length of all the fittings and devices in the refrigerant line. It is common for the equivalent length of all the fittings and devices in the line to add up to 50 percent of the line length.

26.14 AIR-CONDITIONING PIPING PRACTICES

What is considered good piping practice for one type of system may be considered poor practice for another type of equipment. In general, the piping recommendations for air-conditioning equipment are somewhat different from the piping recommendations for commercial refrigeration. Most air-conditioning manufacturers do not recommend oil traps, double risers, or expansion loops in their refrigeration lines. In general, air-conditioning piping should be kept as straight and simple as possible. Most air-conditioning manufacturers recommend that refrigerant lines not be run underground. Lengths of underground lines create a large, cool trap to condense significant quantities of refrigerant during the off cycle. This refrigerant is then delivered to the compressor as a liquid slug on startup.

26.15 PREVENTING LIQUID SLUGGING

Slugging is a momentary return of a quantity of liquid to an operating compressor. A slug can be either refrigerant or oil. To learn how to prevent liquid slugging, it is first necessary to understand what happens in a simple system when the compressor stops operating after its cooling requirements are satisfied. The evaporator is still filled with refrigerant—part liquid and part vapor. There will also be some oil present. The liquid refrigerant and oil may drain by gravity to points where, when the compressor starts running again, the liquid will be drawn into the compressor and cause liquid slugging. The piping design must prevent liquid refrigerant or oil from draining to the compressor during shutdown. When the compressor is above the evaporator, this is not a problem. When the compressor is located in an area where the ambient temperature is cooler than the condenser and/or evaporator, off-cycle refrigeration migration can be a problem. Traps in the discharge piping may be required as well as suction-line accumulators and crankcase heaters. It is best to avoid such problematic conditions where possible rather than to try to design fixes for them after the fact.

Figure 26-13 Feet of equivalent length for copper fittings and valves in feet of copper tubing of same size.

Figure 26-14 Many manufacturers require that the suction line rise above the height of the evaporator when the compressor is installed level with, or below, the evaporator coil.

TECH TIP

Soft refrigeration copper comes in coils, and when properly unrolled it is relatively straight. However, if the copper is simply pulled from the center like a spring, it will have a series of loops. The loops are not significantly deep, but each loop can collect a small amount of refrigerant oil. When the amount of oil in the loops gets large enough, it will begin moving from the first loop to the second, where it picks up that oil and moves to the next. This moving slug of oil then can pass into the compressor and slug it. It moves much in the same way as the last bit of juice is sucked through a child's curlicue straw.

The greater the system refrigerant charge, the more likely it is that compressor failures may be experienced. Common sense dictates close coupled systems with clean, simple piping layouts and minimal refrigerant charges.

Some evaporator coils are designed to feed refrigerant at their top and take suction off the bottom. For top-fed coils, a riser to at least the top of the evaporator must be placed in the suction line if the compressor is below the evaporator, as in Figure 26-14. This inverted loop is to prevent liquid draining from the evaporator into the compressor during shutdown. A hard-shutoff expansion valve will also help prevent refrigerant flow back to the compressor during the off cycle. The sump at the bottom of the riser promotes free drainage of liquid refrigerant away from the TEV bulb, thus permitting the bulb to sense suction-gas superheat instead of evaporating liquid refrigerant. No loop is required for coils that feed at the bottom and take the suction off the top.

26.16 SIZING LINES FOR RESIDENTIAL AIR CONDITIONING

The importance of following the equipment manufacturer's instructions when sizing and installing refrigeration lines cannot be overstressed. Differences in equipment design and application can require different approaches to line sizing. However, there are several design issues that most all residential air-conditioning systems have in common.

Refrigeration lines have a practical limit in terms of both length and size. For safety reasons, hermetic compressors have a system charge limit (Figure 26-15). The charge limit is the maximum amount of refrigerant that the entire system can have in it for safe compressor operation. Extremely long or oversized lines can increase the amount of refrigerant in the system past the safe charge limit of the hermetic compressors used in residential equipment. The "soak out" limit is the maximum charge the oil in the compressor can absorb and not experience liquid slugging on startup.

Further, the compressor has a limited amount of oil. Extra-long or oversized lines can hold so much oil that the compressor becomes low on oil. Adding oil to hermetic compressors is not a viable option because the crankcase of most hermetic compressors is not large enough to hold any extra oil. Residential air-conditioning equipment manufacturers specify the correct line size for their equipment in the installation instructions. Typically, the size for lines less than 50 ft is the same as the condenser stub-out. Lines longer than 50 ft or having a vertical lift more than 20 ft generally require special installation considerations. Figure 26-16 shows one manufacturer's recommendations for line sizes in residential long-line applications.

26.17 LONG-LINE AIR-CONDITIONING APPLICATIONS

Another difference between air conditioning and commercial refrigeration is the definition of a long line set. For residential air conditioning, refrigerant line lengths exceeding 80 ft or having a vertical rise of 20 ft are considered “long.” A 100-ft line set would not be considered particularly long in

a commercial refrigeration system. Consequences of using a long line set include the following:

- Additional refrigerant charge is required.
- Refrigerant migration control is needed.
- Oil return can become a problem.
- Significant system capacity losses are inevitable.
- Metering device adjustments are required.

System modifications that may be required to alleviate problems caused by a long line set include:

- Adding a liquid line solenoid at the outdoor unit. The liquid solenoid closes, preventing refrigerant flow from the condenser to the evaporator during the off cycle.
- Using a hard-shutoff TEV at the evaporator, which prevents migration from the evaporator to the compressor during the off cycle.
- Adding a compressor crankcase heater. The crankcase heater is used to reduce migration to the compressor crankcase during the off cycle by keeping the oil warm.
- Adding a compressor hard-start kit. The hard-start kit is required to get start the compressor against the pressure difference that is created by installing the solenoid and hard-shutoff expansion valve. It will also help the compressor start against the pressure created by a standing column of liquid in the liquid line.

At least one major equipment manufacturer recommends using only a $\frac{3}{8}$ -in liquid line regardless of the length. The system subcooling will have to be high enough to offset the loss through the liquid line. Even with these modifications, the system capacity will be reduced. System capacity reduction from a long line set can be up to 17 percent (Figure 26-16).

26.18 COMMERCIAL REFRIGERATION PIPING PRACTICES

The refrigerant lines for commercial refrigeration systems are typically longer than the lines in air-conditioning systems. Commercial refrigeration systems frequently have multiple components installed on a common piping system, something that is unusual in air-conditioning systems. Underground lines are avoided in air-conditioning applications but are unavoidable in large supermarket installations. Finally, the evaporator saturation temperatures in commercial refrigeration systems are considerably lower than in air conditioning. These differences create unique challenges for commercial refrigeration piping. Oil traps, double risers, and expansion loops are all typical components of a commercial refrigeration system piping layout.

26.19 OIL TRAPS

Some manufacturers recommend oil traps on vertical risers to ensure oil return up the riser. The oil trap, often called an oil lift, is located at the bottom of a riser. The free oil droplets and oil on the side of the riser are blown upward by the velocity of the refrigerant. But the higher the oil is pushed, the slower it travels. Given enough height, some of the oil will stop moving upward and begin to fall back down. The oil lift will fill with oil. The refrigerant velocity through the trap will increase due to the reduced area for the gas to flow through. This increased velocity helps the vapor entraining the oil carry it up the riser. An inverted trap should be used at the top of the line to keep the oil from draining back down once it has made it up the riser. Figure 26-17

Figure 26-17 Suction risers should have an oil trap at the bottom and an inverted trap at the top.

shows how to pipe a vertical suction riser with an oil lift at the bottom and an inverted trap at the top.

Where the vertical rise is over 10 ft on either suction or discharge lines, it is recommended that line traps be installed approximately every 20 ft so that the storage and lifting of oil can be done in smaller stages.

SERVICE TIP

It is important to note that not all manufacturers consider oil traps and double risers good piping practice. Instead, they stress sizing for proper velocity and leaving off the traps. They point out that the extra restriction added by the traps increases the pressure drop through the line. Always follow the manufacturer's recommendations for the particular equipment being installed.

26.20 VERTICAL RISERS IN MODULATING SYSTEMS

Riser sizes for both suction and hot-gas lines are critical to permit carrying the oil upward with the force of the flowing gas. Vertical risers require a higher velocity than horizontal lines. The minimum velocity for a vertical riser is typically twice the minimum velocity of a horizontal line the same size. The increased velocity for vertical risers is often accomplished by using a smaller size for the riser than for the rest of the system. Vertical drops (flow down) will return the oil by gravity and are not critical as to size or velocity.

TECH TIP

Commercial systems often operate at varying capacities. That is, the compressor is not always moving the same amount of refrigerant. Compressor capacity is reduced to match the cooling load. Operating at a reduced capacity is called part load operation.

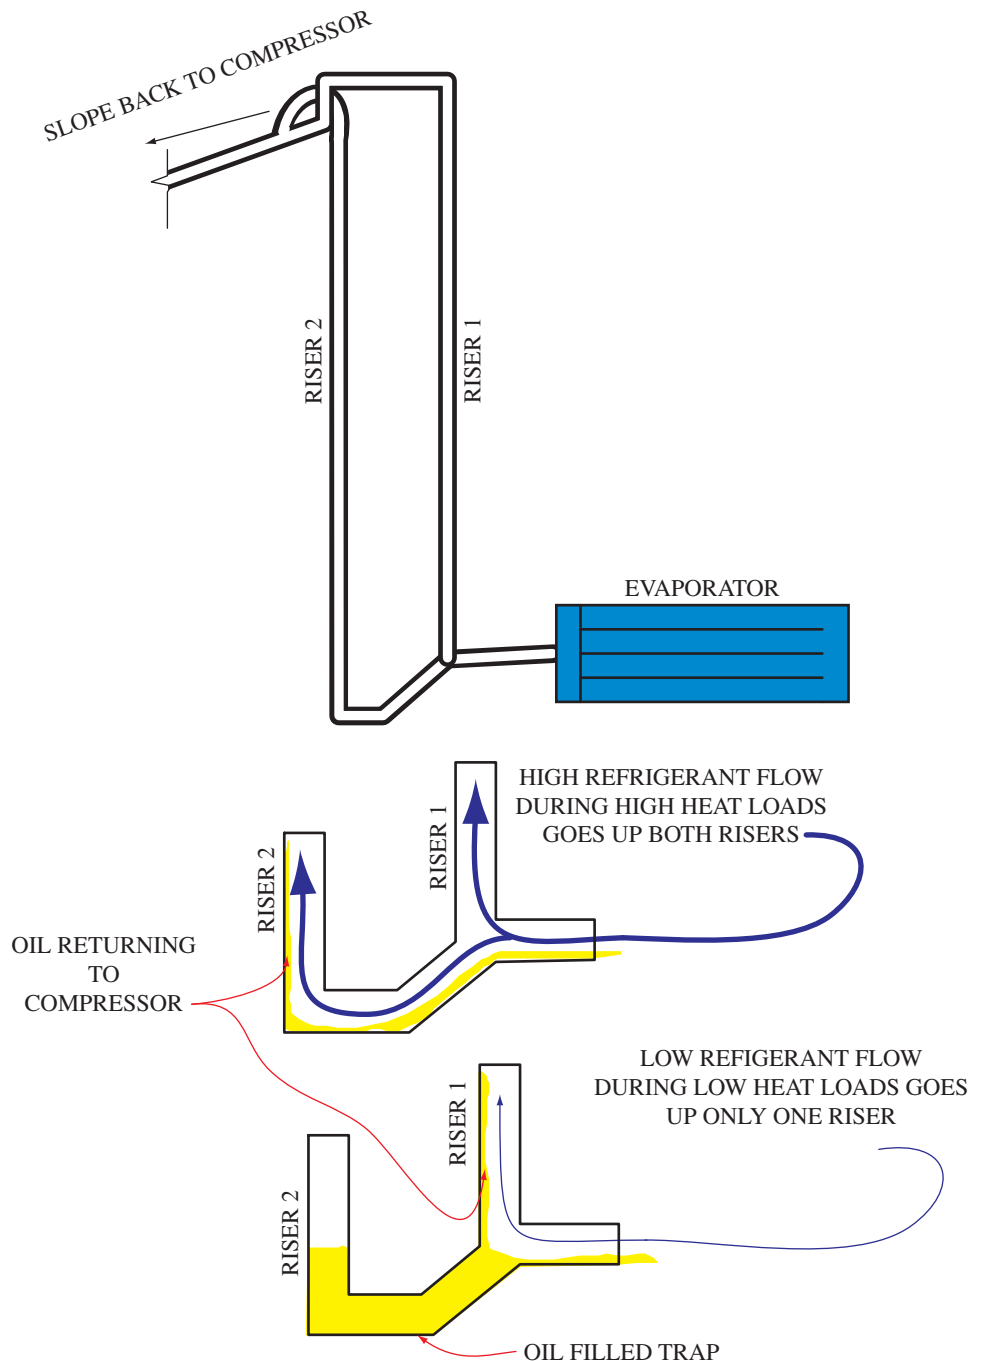

As system capacity reduces, so does the velocity of the refrigerant traveling through the lines. If the compressor is equipped with capacity control, the vertical riser can be sized to return the oil when the system is running at its minimum capacity. Short risers on systems with capacity control will usually be sized smaller than the remainder of the suction line (see Figure 26-12). This helps keep the velocity up without adding too much pressure drop to the overall system. Although this smaller pipe has a higher pressure drop, its short length adds a relatively small amount to the overall suction-line pressure drop.

An alternative to sizing the riser for minimum capacity is to provide a double riser in the suction line, as illustrated in Figure 26-18. If a double riser is used, additional oil is

required in the system to fill the trap during periods when the overall capacity of the system is reduced, and only one riser is used. When full capacity is resumed, this extra oil can return to the compressor and overload the oil capacity of the crankcase, causing oil slugging. It is, therefore, desirable to avoid the use of double risers wherever possible.

The smaller riser should be sized for a minimum velocity of 1,000–1,500 FPM at the system's minimum capacity. The larger riser should be sized to carry the remaining system capacity at a minimum velocity of 1,000–1,500 FPM. Referring to Figure 26-18, riser 1 is used to carry the suction gas at minimum load. Riser 1 plus riser 2 are used to carry the suction gas at maximum load. The area of riser 1 plus the area of riser 2 is made equal to the area of the main suction line.

Figure 26-18 Double-suction riser.

Both risers will carry refrigerant and oil when maximum cooling is required. During part load operation, as the amount of refrigerant being evaporated decreases, the gas velocity will also decrease to a point where it will not carry oil up through the larger riser. Oil will collect in the trap and force the refrigerant to flow up the smaller riser, which is sized for the minimum system capacity (see Figure 26-18). As the system load increases and more refrigerant is passed through the evaporator, this increased pressure will break the oil seal in the trap and carry oil upward through both risers.

SERVICE TIP

Small, high-speed compressors have relatively small crankcase capacities. If double risers with oil seals are to be utilized, it may be necessary to add an auxiliary oil receiver. Be sure the system has sufficient oil to permit proper compression lubrication at full and minimum capacities.

Figure 26-20 This discharge check valve keeps liquid refrigerant from draining down on top of the compressor head during the off cycle.

26.21 OFF-CYCLE PROTECTION

When a remote condenser is being used and it is located higher than the compressor, the hot-gas discharge line should not be piped directly up from the compressor. This makes the compressor head an oil and refrigerant trap.

Some oil is always in this line because it is being pushed along with the refrigerant vapor. A vertical riser directly from the compressor would allow oil to drain back to the compressor when it stops. Liquid refrigerant can be formed in the hot-gas line in the winter. In cold weather, once the compressor cycles off, the hot-gas line can be cooled to a temperature below the dew point of the refrigerant. This can result in liquid refrigerant being formed in the hot-gas line. Either oil or liquid refrigerant can break valves on a reciprocating compressor on startup.

To prevent this, a discharge loop can be placed in the hot-gas line with an optional check valve (Figure 26-19).

Figure 26-19 Discharge line risers should have a trap at the bottom to prevent liquid accumulation in the compressor head.

Modest quantities of oil and liquid refrigerant can accumulate in this trap when the compressor shuts down and will be dissipated on startup without damage to the compressor.

A discharge check valve is essential for systems with large quantities of refrigerant and a condenser that is located above the compressor. Figure 26-20 shows a discharge check valve on a transport refrigeration unit.

26.22 OIL RETURN IN PARALLEL-COMPRESSOR SYSTEMS

Parallel compressors are often used to provide systems that can produce different levels of cooling capacity based on system need. When demand is heavy, all of the compressors will be operating; but as the load decreases, one or more of the system compressors can be cycled off.

TECH TIP

Keeping the oil level balanced between parallel compressors can be a problem. Oil-level control systems are used with multiple-compressors systems to ensure proper oil level in each of the compressors. If the oil level is too low, compressor lubrication can be lost and the compressor can be damaged or destroyed. If the oil level is too high, the crankshaft will be pushed through the oil. This will cause excessively high current draw, which can damage or destroy the compressor motor.

In parallel compressors, one of the main problems is returning the oil back to the crankcases of each of the compressors. Without consideration for oil return and equilization, some compressors will end up with too much oil while others have too little oil. Maintaining the oil level in each compressor crankcase is important for reliable operation. The compressors should be mounted on the same level;

Figure 26-21 Typical oil equilibration piping for multiple compressors.

normally they are mounted on a rack. A compressor rack is a frame constructed from structural steel, angle iron, or square tubing.

Figure 26-21 shows an oil-equalization piping system for multiple compressors. Two separate pipe systems are required to provide for oil-level distribution. One pipe is connected into the bottom of the compressor. This pipe is called the oil-level equalization line. Another pipe is attached to the upper portion of the compressor crankcase, the crankcase pressure equalization line. The lines are to be installed as follows:

- The crankcase oil-equalization lines are screwed into the bottom ports of the crankcase. The lines must be the same diameter as the bottom ports. These lines tie into a crankcase-equalization manifold. The manifold should be mounted below the crankcase to prevent any vapors from entering the manifold. If vapor were to enter the manifold, it would prevent the oil from being equally distributed to the compressors' crankcases.
- The crankcase-pressure equalization line is attached between the compressor and a manifold. The manifold must be higher than the top of the crankcases. This is to prevent any liquid (oil) from entering the manifold, which would also prevent equal distribution of oil to each crankcase.

There should be isolation valves on each of the equalization lines next to each compressor. This is to allow each compressor to be isolated for servicing. The manifold method is the preferred method of oil return because it can transfer oil from one crankcase to the other in case one crankcase has too much oil.

26.23 OIL-LEVEL CONTROL

Oil-level controls can also be used to return oil to the compressor. Figure 26-22 shows piping for an oil-control system using an oil separator and oil-level controls. This is done by first piping the hot-gas line to an oil separator. The outlet of the oil separator is piped to an oil receiver. In the receiver, any liquid refrigerant is vaporized. It is vaporized because there is a line connecting the receiver to the suction line. This lowers the pressure in the receiver. A pressure-differential check valve maintains the pressure in the receiver to a point slightly higher than what the pressure is

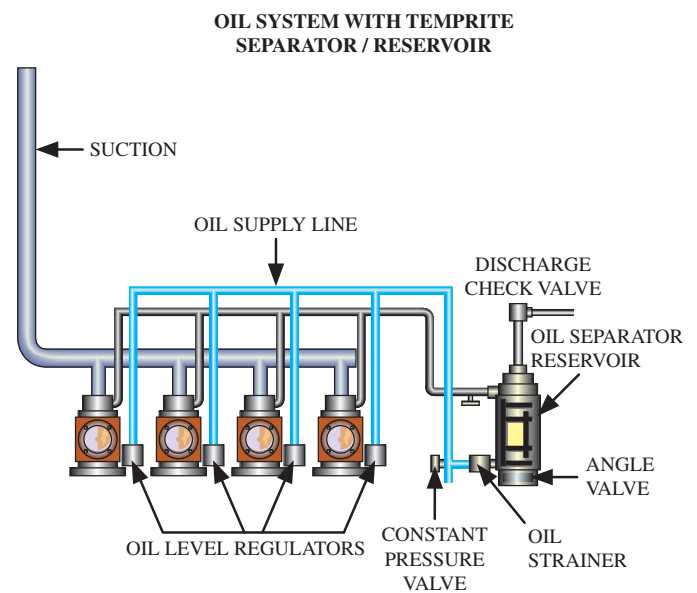

Figure 26-22 Typical oil-control system for multiple compressors.

in the crankcase. This slightly higher pressure allows oil to flow from the receiver to the crankcase level controls. As the oil level drops in the crankcase, the level controls open and allow oil to flow into the crankcase.

This oil-level control cannot lower the oil level in a compressor crankcase if the oil level becomes excessively high.

26.24 PIPING FOR MULTIPLE EVAPORATORS

Systems with multiple evaporators have a common liquid line and a common suction line. The evaporators are individually piped to these common lines. Care must be taken to ensure that flow from one evaporator does not affect the operation of other evaporators. When evaporators are stacked vertically, oil and liquid can drain out of the top evaporator into the bottom evaporator, as in Figure 26-23. This can affect the expansion valve bulb, causing the valve to throttle and starve the bottom evaporator. The suction lines should be piped as shown in Figure 26-24 so that liquid cannot drain from the top evaporator into the bottom evaporator.

Figure 26-23 Liquid can drain from the top evaporator to the bottom evaporator with incorrectly piped evaporators.

Figure 26-24 Properly piped evaporators prevent liquid from draining into the lower evaporator.

Evaporator pressure regulators are required when multiple evaporators with different temperatures are piped to a common suction line. Each evaporator will have a pressure that corresponds to its saturation temperature. This means that evaporators with different pressures will all be piped into the same suction line. Evaporator pressure regulators keep the pressure in each evaporator from dropping below the correct operating pressure for that evaporator. The common suction line must be at or below the pressure of the lowest temperature evaporator.

26.25 COMMERCIAL REFRIGERATION LINE SIZING

Charts called nomographs are used to size refrigerant lines in commercial refrigeration and air-conditioning applications. Each refrigerant has two nomographs: one for pressure drop and one for velocity. Typically the line size required to meet the maximum pressure-drop requirements is selected and the refrigerant velocity is checked to see that it falls between the minimum and maximum recommended velocities. The five factors needed to use a nomograph are the type of refrigerant, the length of the line in equivalent feet, the capacity of the unit, the condenser temperature, and the allowable pressure drop.

Figure 26-25 shows a simplified velocity nomograph. To use the nomograph, find the system capacity at the top right-hand side of the chart. There are diagonal lines representing different temperature suction lines, the discharge line, and finally the liquid line. Follow the vertical capacity line straight down until it intersects the diagonal line representing the evaporator temperature (see the red line in Figure 26-25). On the left side of the chart are diagonal lines representing different sizes of pipe. Go horizontally across from the intersection until this line intersects the pipe size being checked (see the blue line in Figure 26-25). Drop straight down to the answer at the bottom left side of the chart (see the green line in Figure 26-25). In the case of pressure-drop nomographs, this will be the pressure drop per 100 ft of pipe. In the case

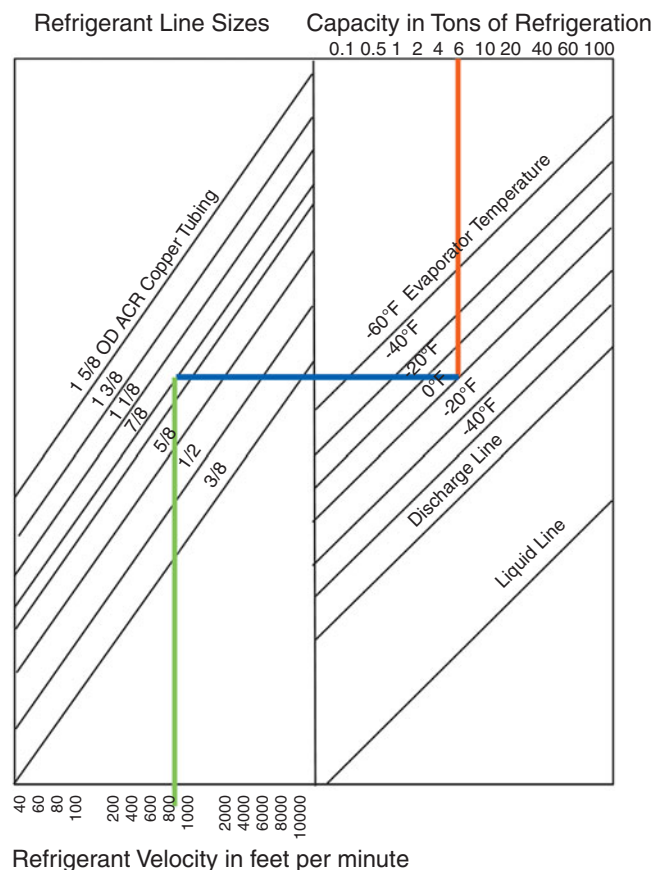

Figure 26-25 Nomographs like this are used to determine the velocity of refrigerant through refrigeration lines.

26.26 QUICK LINE SELECTION TABLES

Some commercial refrigeration equipment manufacturers publish quick refrigeration-line-sizing tables. These tables make assumptions about the type of refrigerant, condenser temperature, evaporator temperature, and line length. They are produced by application engineers who take the assumptions being used for a particular chart and use line-sizing nomographs to determine the correct line size. These are accurate as long as the assumptions made fit your particular application. Figure 26-26 shows a typical quick sizing chart. This chart is for a system using R404a with a condensing temperature of 105°F and evaporator temperatures ranging from -10°F up to 50°F. Notice that the line sizes increase in diameter as the line lengths increase.

26.27 REFRIGERANT LINE INSULATION

It is always good practice to insulate the suction line since it is usually lower in temperature than the surrounding air and can condense moisture. Insulation should be applied and thoroughly sealed with a good moisture barrier to prevent condensation on the outside of the pipe or in the insulation. On most systems, the suction line is the only line that

is insulated. However, there are times when the liquid and hot-gas lines need to be insulated, too. The insulation needs of the piping are summarized in Figure 26-27.

All refrigerant-line insulation should be closed cell to reduce the adsorption of water. Closed cell means that the material is made of millions of tiny gas pockets that are each completely sealed. This keeps the material from wicking up moisture and also allows it to act like a moisture barrier. Two types of pipe insulation are commonly used: buna-N elastomeric rubber and polyolefin. The elastomeric rubber is soft and very flexible. Its flexibility makes it difficult to cut, even with a razor knife. The polyolefin insulation is somewhat flexible but is considerably more rigid than the rubber product. It is easier to cut but does not conform to bends as well as the rubber product. Both are available in wall thicknesses ranging between $\frac{3}{8}$ in to $1\frac{1}{2}$ in and come in unsplit or split form (Figure 26-28).

For new lines, the unsplit insulation is slid over the end of the tubing before the tubing is connected (Figure 26-29). This form of pipe insulation typically has a fine white powder lubricant on the inside to make it easier to apply. Try to avoid getting the powder inside the pipe while pulling the insulation over it.

The split insulation can be applied after the pipe is in place. Some has self-adhesive strips to join the insulation; other types must be glued with a special cement made for the pipe insulation. In addition, the ends of the insulation should be glued together where they join.

Figure 26-29 Pipe insulation that is not split is placed on the copper tubing before the pipe is connected to the system.

Suction-Line Insulation

Insulation on the suction line is an absolute requirement. Suction-line insulation eliminates condensation on the line and helps improve system efficiency by preventing the suction line from picking up heat from the surrounding air. Water condensing on the suction line can drip and can cause damage to ceilings, floors, furnishings, and electronics. Insulating the suction line helps keep the suction-gas temperature as low as possible. Hermetic and semihermetic motor compressor assemblies are suction-gas cooled. Lower return gas temperature is better for cooling the motor and keeping the discharge temperature down.

Heat Pump Gas-Line Insulation

Some types of insulation that are acceptable for suction-line insulation are not able to withstand the high temperatures of the gas line on a heat pump when it is operating in heat. Generally speaking, lines on heat pumps are usually insulated with elastomeric rubber insulation; polyolefin insulation material is not used for heat pumps. Make sure that insulation used on the large gas line of a heat pump system is rated for heat pump duty.

TECH TIP

The joints in the insulation on suction lines must be sealed. Often technicians have the misconception that the insulation is simply there to aid in system efficiency. That is only partially true. Because the refrigerant line is below the dew point, moisture can condense on the line. If the insulation vapor barrier is not sealed, water can collect around the copper and draw in through gaps and openings at the joints. The water can then run down the refrigerant line set and weep out, causing water stains and mold growth in the wall cavities. It is important that the seams of the refrigerant-line insulation be sealed properly.

Liquid-Line Insulation

Normally, no insulation is used on the liquid line because the liquid line is usually warmer than its surroundings. Allowing the liquid line to lose heat to the air actually improves performance by increasing subcooling. However, when the liquid line runs through a hot space such as an attic, insulation of the liquid line may be required to prevent boiling from occurring prior to the expansion valve.

Insulation on the liquid line of a computer room air-conditioning system is desirable. The liquid can get quite cold in winter, and lines running through humidified space to the air-conditioning unit will sweat and drip if not covered.

Sometimes the liquid line can be insulated together with the suction line to promote heat exchange between the two lines for long-line applications. The extra subcooling the liquid line receives from the suction line helps to prevent flash gas in the liquid line.

Hot-Gas-Line Insulation

In package units and condensing units with short hot-gas lines between compressor and condenser, no insulation should be used on the hot-gas line.

On remote condensers, insulating the hot-gas line is advisable. If the unit is expected to operate in low outside temperatures, it is possible to reach the condensing temperature of the discharge refrigerant before the refrigerant reaches the condenser. This can cause liquid slugs to fall backward down the hot-gas line into the superheated vapor from the compressor. Violent expansion of the slug vaporizing can cause "steam hammer," resulting in noise and vibration, even to the point of line breakage. Insulating the hot-gas line would prevent this action.

When hot-gas lines are run indoors in machinery rooms, they should be insulated or otherwise protected to prevent accidental burns to operating personnel.

Be sure to use an insulation that can withstand high temperatures if a hot-gas line is insulated.

26.28 PIPING SUPPORTS

All piping must be properly supported (Figure 26-30). The supports must allow for the expansion and contraction of the pipe. The recommended allowance is $\frac{3}{4}$ in of movement

Figure 26-30 Maximum spacing between supports for type-L copper tubing.

OD Pipe Diameter (in)	5/8	7/8	1 1/8	1 3/8	1 5/8	2 1/8	2 5/8
Maximum Span (ft)	5	6	7	8	9	10	11

Figure 26-31 Proper support for piping.

per 100 ft of pipe. Hangers should be spaced according to the pipe size being supported. Figure 26-31 shows the recommended distances between supports for common sizes of copper pipe.

Piping should always be supported near a bend in the piping, preferably on the longest straight connection to the

bend. The hanger must have sufficient width not to crush the insulation on insulated pipe. Extra rigidity must be incorporated into the insulation at the pipe clamp because the insulation will compress under the weight of the pipe. Sheet-metal saddles or wood-block inserts (on large piping) will serve this purpose (Figure 26-32).

26.29 VIBRATION DAMPENERS

It is usually desirable to isolate vibrating equipment to reduce noise and to prevent damage to the piping or other equipment. With soft copper tubing, loops or a coil of tubing can be connected to the moving part. For hard copper tubing, a similar dampening effect can be produced by running the suction and discharge lines 15 times the pipe diameter in each of two or three directions before securing the pipe hanger. This will provide some give to the piping without undue strain. Flexible connectors at the compressor can help isolate the refrigerant piping from compressor vibrations and movement (Figure 26-33).

For larger equipment, rubber-in-sheath or spring vibration-eliminator mounts and flexible piping connections can be provided for the compressor to supply the necessary isolation. Concrete inertia blocks are sometimes incorporated into the base. Piping and electrical lines must be securely anchored beyond the isolators to be effective.

26.30 HOT-GAS MUFFLER

The pulsations from a compressor, usually a reciprocating type, can cause serious vibrations and noise in the hot-gas line. This can be most noticeable where a remote air-cooled

Figure 26-32 Wood pieces are inserted into the insulation to support the pipe at each pipe hanger.

Figure 26-33 This refrigeration piping on this system is isolated from the vibration of this compressor by flexible connectors at the compressor.

condenser requires a long vertical hot-gas line. Usually the larger the compressor, the more noticeable the pulsations, although this is dependent on speed and number of cylinders.

The best way to solve this problem is to install a hot-gas muffler in the compressor discharge line, as shown in Figure 26-34. The hot-gas muffler should be placed in a vertical position (so that it does not trap oil), as close to the compressor as possible, and securely mounted to the compressor. This usually destroys the resonance that the compressor has built up in the hot-gas line. If this does not

help, it may be necessary to enlarge the discharge line and relocate it, to destroy the resonance pattern.

UNIT 26—SUMMARY

The sizing of the refrigerant lines is important for many reasons. If the lines sizes are too small, the system will lose efficiency. If the line sizes are too large, the system may destroy itself due to slugging or oil starvation.

Pressure drop through the refrigerant lines kills system efficiency. The typical maximum pressure drop through any line is equivalent to a 2°F saturation temperature drop. Refrigeration vapor lines must also be sized to create a high enough velocity for the refrigerant vapor to carry the oil back to the compressor. Typical minimum horizontal line velocities are 500–750 FPM. Typical minimum riser velocities are 1,000–1,500 FPM. Minimizing pressure drop and ensuring oil return are sometimes in conflict. Larger lines minimize pressure drop, but smaller lines increase velocity to ensure oil return. Oil return should always take precedence.

Proper insulation of the various types of refrigerant lines will improve efficiency, and system efficiency is critical for customer satisfaction. A properly insulated piping system can also eliminate operational problems. Piping support is necessary to eliminate potential problems, including undesirable vibration. Vibration can cause both noise complaints and pipe failures.

Customer Complaint: Compressor Keeps Cutting out on the Low-Oil Safety

Equipment Type: Low-Temperature Walk-in

You arrive at the small butcher shop to find the walk-in warm and the compressor off on oil safety. In talking to the owner you learn that the compressor is on top of the walk-in and the condenser is located on the roof. You also learn that the box had been set to hold the temperature at 40°F up until last month, when it was converted to a low-temperature walk-in with a 0°F setting.

When you inspect the walk-in and compressor, you see that the last technician had made all of the necessary changes and additions to the compressor and evaporator, including adding a defrost control.

Knowing that the compressor oil had to be in the system, you suspect that the evaporator is oil logged. You start the compressor and note that the oil level quickly rises in the compressor-oil sight glass. After a few minutes, the oil level is stable at ½ the oil sight glass. The system has the correct amount of oil.

When you examine the new evaporator, you note that the tech used the original piping. A quick check of the evaporator and compressor technical specification

indicates that the low-temperature application has resulted in a lower refrigerant velocity in the suction line. You have determined that the refrigerant line is too large. The flow in the suction line is below 500 FPM.

Because the compressor is only a short distance above the evaporator, you can easily change the suction line with a smaller line to increase the velocity. Once you have replaced the suction line, the walk-in runs properly.

Customer Complaint: Poor Cooling

Equipment Type: Residential Split System in Third-Story Apartment, Condenser on Ground

A customer complains that their air-conditioning system cannot cool the apartment on a hot day. She notes that her neighbor two stories below has the same size apartment and the same type of unit, and it never has a problem. The lines run up three stories to get from the condenser on the ground to the evaporator in the attic.

The technician notices that even though the system has a vertical rise of 30 ft, the system has not been modified for a long-line application. The technician changes the fixed-restriction metering device to a hard-shutoff expansion valve, adds a liquid-line solenoid at the condenser, adds a hard-start kit, and charges the unit until the subcooling is high enough to overcome the pressure drop from the high vertical lift.

The system cools better, but it still must run longer than the downstairs neighbor's unit because of the added heat load of the upstairs apartment and the reduction in system capacity even after the modifications.

Service Ticket 2403

Customer Complaint: Multiple Compressor Failures

Equipment Type: Residential Split System on Ground Level with Lines Run Underground

A technician is asked to look at a system that has experienced multiple compressor failures. The house has a concrete-slab floor and an exposed-beam vaulted ceiling. The air-conditioner blower coil sits in the middle of the house, and the refrigerant lines run under the slab for about half of the length of the house. The compressor failures are always mechanical.

The technician decides that the compressors are probably dying from liquid slugs due to the long line set run underground. However, there is no alternate path for the lines due to the house construction. The technician suggests treating the system like a long-line application and also adding a suction accumulator to protect the new compressor. The additions of a liquid-line solenoid at the condenser and a hard-shutoff valve on the evaporator reduce the migration during the off cycle. The accumulator keeps the occasional slug from reaching the compressor. A hard-start kit is also added to help

the compressor start against pressure. Two years after the modifications, the new compressor is still operating without incident.

Customer Complaint: Higher than Expected Power Bills

Equipment Type: New High-Efficiency Residential Split-System Change-out

A customer has just purchased a new 2-ton 16-SEER high-efficiency air conditioner to replace his 25-year-old system. To the customer's surprise, it costs about the same to operate as the old unit. The installing contractor changed both the indoor and outdoor sections but used the existing line set. The original line set had a 1/4-in liquid line and a 5/8-in suction line. The technician notices that the new system has line stub-outs for a 3/8-in liquid line and a 7/8-in suction line. The installers used sweat reducers to connect the system up to the old line set. The technician checks the manufacturer's literature, and it specifies a 3/8-in liquid line and a 7/8-in suction line. The technician notices that the liquid line is warm leaving the condenser and cool before it enters the evaporator. The technician explains that the small size of the old line set is causing enough pressure drop to create flash gas in the liquid line and reduce the system capacity, which causes it to run longer. The system operates correctly after replacing the old lines with the correct size liquid and suction lines.

Accessing Sealed Refrigeration Systems

OBJECTIVES

After completing this unit, you will be able to:

1. describe the different types of refrigeration service valves.
2. explain the operation of gauge manifold valves.
3. explain how to properly install and remove a gauge manifold set on manual service valves.
4. explain the operation of split-system installation valves.
5. explain how to properly install and remove a gauge manifold set on Schrader valves.
6. describe how to gain access to systems without service valves.

27.1 INTRODUCTION

One of the last things a service technician should do when troubleshooting a system is attach a set of gauges to the system. Each time a sealed system is accessed, there is a chance that some contaminants can be introduced to the system or refrigerant can be lost. However, there are times when a refrigeration system's operating conditions cannot be accurately assessed without accessing the system's refrigerant piping to determine the pressures. Knowing the temperature difference across the coils, the amperage, and the airflow all give the technician vital information; but sometimes a final determination of the problem cannot be accurately made without knowing the system operating pressures.

It is important to attach and remove a gauge manifold set properly. Understanding how to properly manipulate system access valves and install gauge manifolds is vital to the personal safety of the service technician. Improper technique can damage the system or injure the technician. Proper techniques should always be practiced so that they become a habit performed the same way each time.

SAFETY TIP

The proper personal protective equipment (PPE) for installing refrigeration gauges and manipulating valves includes safety glasses and gloves. When liquid refrigerant escapes into the atmosphere, it boils at extremely cold temperatures. Liquid refrigerant sprayed in the eyes can cause blindness, and sprayed onto the skin it can cause frostbite.

27.2 FACTORY-INSTALLED SERVICE VALVES

With the implementation of the Clean Air Act, all manufacturers are required to provide factory-installed service valves on Type II and Type III equipment. Type I equipment is only required to have a process stub. Commercial refrigeration and

air-conditioning systems have had factory-installed service valves for years.

SERVICE TIP

You must put service valve caps back on all access ports. This is an EPA refrigerant management requirement. Failure to do so is a violation of EPA rules and regulations. Many service access valve caps have O-rings to seal the system. Be sure these O-rings are in place before installing the cap to ensure a proper seal. Caps that have a metal-to-metal seal must be tightened one-eighth turn with a wrench after they have been finger-tightened.

Factory-installed service valves may be a manually operated stem shutoff valve, as in Figure 27-1, or a Schrader-type valve. Schrader valves are spring-loaded valves similar to the valves used on car tires. They have a core that threads down into them (Figure 27-2). Refrigerant is allowed to flow into and out of the valve when the core is depressed. To

Figure 27-1 Manual three position service valve.

Figure 27-3 Schrader valves should always have their cap on when not in use.

prevent leaks, Schrader valves should always have their valve caps on when not in use (Figure 27-3).

Residential split-system equipment service valves are usually located on the suction line and liquid line (Figure 27-4). The valve on the suction line is used to read the low-side system pressure, and the valve on the liquid line is used to read the high-side system pressure. Most air-conditioning systems use front-seating split-system shutoff valves, as shown in Figure 27-5b. These valves are used to hold the system refrigerant in during shipping. The gauges connect to the Schrader valve that is built into them. These valves are normally opened when the unit is installed and then seldom used after that. It is not necessary to turn them to read pressure because the Schrader valve in them reads line pressure regardless of the valve position.

SAFETY TIP

A few residential split systems use manual stem valves as shown in Figure 27-5a. The gauge connection on these valves is not a Schrader valve. These valves must be opened to read pressure. More important, they must be *closed* before removing the gauges.

Figure 27-4 Residential split-system installation valves.

(a)

(b)

Figure 27-5 Service valves.

Figure 27-6 The arrow points to the port that is always on the low side of the system regardless of the operating cycle.

On heat pump systems, both lines are on the high side during the heating cycle. To allow technicians to read low-side pressures in heat, heat pump systems use a third valve that is always connected to the low side of the system regardless of the cycle (Figure 27-6). Residential packaged units typically have a low-side and high-side Schrader valve mounted on the outside of the equipment (Figure 27-7).

Commercial refrigeration systems typically have three manual stem service valves. A suction service valve and a discharge service valve are located on the compressor. A service valve called the king valve is mounted on the outlet of the receiver. These service valves are equipped with a gauge service port. Operating refrigerant pressures may be

Figure 27-7 High-side and low-side Schrader valves on a packaged unit.

observed on the service gauge manifold when hoses are connected to these ports and the valves are cracked open.

27.3 THREE POSITION SERVICE VALVES

Three position service valves have three ports and two seats. The three ports include a middle port that connects to the compressor or system, a line port that connects to the refrigerant line, and a service port that is used for servicing the system (Figure 27-8). The refrigerant has three ways it can take through the valve: it can flow between the middle port to the line port, the middle port to the service port, or

Figure 27-8 Three position system service valve.

Figure 27-9 Three position service valve in the back-seated position.

between all ports. There is not a closed position on these valves because one of the two exit ports will always be open. Instead, the terms *back-seated* and *front-seated* are used to describe the valve positions.

The valve is back-seated when the stem is turned all the way out counterclockwise. This position is called back-seated because the valve is seated on the back port of the valve. In this position, the service port is closed but the middle port is open to the line port (Figure 27-9). Service valves should always be placed in the back-seated position before installing or removing gauges.

The valve is front-seated when the stem is turned all the way in clockwise. This position is called front-seated because the valve is seated on the front port of the valve. In this position, the line port is closed but the middle port is open to the service port (Figure 27-10). The front-seat position can be used to isolate refrigeration system components.

SAFETY TIP

Be sure that internal pressure in the compressor is relieved by recovery and vacuum procedures before attempting to remove an isolated compressor from the system. Pressure remains in the compressor even after the service valves are front-seated.

Figure 27-10 Three position service valve in the front-seated position.

Figure 27-11 When a service valve is cracked, the valve is just off of the seat, creating a small opening, or crack.

If the stem is positioned anywhere in between the back-seat and front-seat positions, all three ports will be open. Turning the valve one-half turn off of a fully seated position is called *cracking the valve*. When checking pressures, the valves are usually in the back-seat cracked position (Figure 27-11).

The stems on manual service valves should only be turned with a valve stem wrench (Figure 27-12). The corners of the valve stems round off easily when they are turned with adjustable wrenches or pliers. Once a stem is rounded it cannot be turned with the correct wrench (Figure 27-13). The cap for the valve stem and the cap for the service port should always be replaced after using manual service valves.

27.4 SCHRADER VALVES

Schrader valves provide a convenient method of checking system pressures or servicing the system where it is not economical or convenient to use manual stem service valves. The Schrader valve core, shown in Figure 27-14, is a spring-loaded device for positive seating. The valve is like those used on automobile tires, but the cores used in refrigeration valves are not the same as the cores used in car tires. The

Figure 27-12 Square-stem service valve and valve wrench.

Figure 27-13 This valve stem has been ruined by a careless technician using the wrong tool.

Figure 27-14 Schrader valve core.

rubber used in tire valves is not compatible with refrigerants and would dissolve if used on a refrigeration system.

The stem must be depressed to force the valve seat open against spring pressure. Refrigerant hoses with built-in core depressors must be used with Schrader valves. When a hose with a core depressor is connected to a Schrader valve, the valve core is pushed in and the valve opens (Figure 27-15). Ideally, the seal in the gauge hose will seat just as the depressor is pushed in and very little

Figure 27-15 The core depressor on the refrigerant hose pushes in the Schrader valve core when the hose is connected.

Figure 27-16 This cutaway shows how a Schrader valve works.

refrigerant will escape. Flow through a Schrader valve is limited because the core takes up most of the space in the center of the valve. This leaves only a small passage for refrigerant to go through (Figure 27-16).

If a valve core leaks, it can be replaced by using a core-removal tool to unscrew it. Some tools, such as the one in Figure 27-17, allow this to be done while the system is under pressure. All Schrader valves should have a leakproof cap on them when not in use. The cap can prevent refrigerant loss even if the valve core does leak.

27.5 SPLIT-SYSTEM INSTALLATION VALVES

Most new residential split systems come equipped with unit installation valves, as shown previously in Figure 27-4. These valves are used to hold the refrigerant charge in the

Figure 27-17 This tool can be used to change the core in a Schrader valve without losing the refrigerant in the system.

Figure 27-18 The condensing unit is shipped with the valve front-seated to hold in the system refrigerant.

outdoor unit while it is shipped. These valves have three ports: the port to the unit, the line port, and the Schrader valve service port. Even though they have three ports, they do not behave like standard manual service valves. No ports are closed in the back-seat position; the Schrader valve service port is always open to the line port regardless of the position of the valve.

These valves are used primarily for holding the system charge during shipping. The systems are shipped with the valve run all the way down clockwise (Figure 27-18). After connecting the refrigerant lines and indoor coil, the system is evacuated through the service port. The valve is turned counterclockwise to open it and allow the trapped refrigerant to flow throughout the system. Typically the valve is never used again because it does not control refrigerant flow to the service port.

SAFETY TIP

Be careful when opening split-system installation valves. The only thing that keeps the plug in the valve is a small lock ring at the top of the valve. Stop turning when the valve plug approaches the lock ring. The valve does not need to be tightened in the counterclockwise, or up, position. Overtightening the valve can cause the lock ring to pop out, and the plug will fly out under system pressure, with all the system refrigerant behind it.

27.6 GAUGE MANIFOLD VALVES

The valves on a gauge manifold are used to control the flow of refrigerant from either side of the manifold to the center. Figure 27-19 shows a cutaway view of a gauge manifold. It is not necessary to open the valves on the gauge set to read pressure. The parts above and below each valve are interconnected so the gauges will read pressure at all times when connected to the system. The valves open or close the path from each side to the middle port. When both valves are closed (front-seated) the center or utility port is isolated (Figure 27-20a).

Slightly opening a valve is called cracking the valve. Cracking open the low-side valve connects the low side and center hoses (Figure 27-20b). Some refrigerant can now flow from the center hose to the system. Fully opening the low-side valve opens the low-side port to the center port for full flow of refrigerant or for evacuating the system (Figure 27-20c).

With the low-side valve closed, cracking open the high-side valve will allow some refrigerant to flow from the high side to the center hose (Figure 27-20d). Fully opening the

Figure 27-19 Cutaway of a gauge manifold.

Figure 27-20 Gauge manifold valve positions.

high-side valve opens the high-side port to the center port to remove refrigerant from the system or for system evacuation (Figure 27-20e).

Opening both the low- and high-side valves opens both the low- and high-side ports to the center port. This valve position is used for system evacuation (Figure 27-20f).

27.7 CONNECTING A GAUGE MANIFOLD SET ON MANUAL SERVICE VALVES

SAFETY TIP

Always check the system data plate to confirm the gauge set you are using is compatible with the refrigerant in the system.

Locate the suction service valve. It is usually located on the compressor where the suction line attaches. Check to make sure the service valve stem is back-seated. This will ensure that no pressure is currently applied to the gauge port of the service valve. Remove the gauge port flare cap and attach the hose connected to the compound side of

your gauges to the gauge port. Locate the discharge service valve. It is also located on the compressor, but it is the valve connected to the smaller discharge line leaving the compressor. Check to be sure the valve stem is back-seated. Remove the gauge port cap and attach the hose connected to the high side of the manifold to the gauge access port on the discharge service valve.

The gauge manifold and connecting lines should be purged to avoid system contamination from air and moisture. To purge a unit that does not operate in a vacuum, crack both the suction and discharge service valves. Open the gauge manifold valves one at a time and bleed refrigerant out the middle line until all the air is out. This usually just takes a few seconds. This will purge the gauge manifold and the connecting lines. Many technicians simply loosen the hoses at the manifold connections and purge each hose. However, this does not purge the manifold or middle line.

SAFETY TIP

Contact with the gases being purged should be avoided. Oil and liquid refrigerant will sometimes escape during the purging process, and liquid refrigerant can cause frostbite.

The high side is used to purge both sides of the manifold on systems whose low side is likely to be in a vacuum. To purge from the high side only, connect the lines as before, but crack only the high-side service valve. Open the low-side and high-side manifold valves at the same time and loosen the hose connection at the low-side service valve. This will purge everything but the middle hose. It can then be purged separately by loosening the middle hose at the plug connection. This procedure will work on any system with manual service valves but is only necessary when the low side is likely to be in a vacuum.

SERVICE TIP

With most refrigerants, it is common for the standing pressure on the low side of a system to exceed the normal range of the compound gauge. The retard range protects the gauges from damage when a pressure above their normal range of operation is connected to them. Gauges for R-134a and R-22 typically have a retard range of up to 350 psig.

Some technicians purge the hoses and gauges from a separate refrigerant tank. This has the advantage of not losing any of the system charge. It has the disadvantage of requiring a drum of refrigerant even if you are just checking the pressures. To use this method, connect your gauges as before except connect the middle leg to the refrigerant drum. Do not open the service valves. Crack the tank valve and open both manifold valves. Loosen the refrigerant hoses at both the suction and discharge service valves and purge each individually. After both hoses are purged, close the valve on the refrigerant cylinder and close the manifold valves.

27.8 REMOVING A GAUGE MANIFOLD SET FROM MANUAL SERVICE VALVES

The simplest way to remove the gauge set is to back-seat both the service valves. This should prevent any further escape of refrigerant into the gauges. There is still a considerable amount of refrigerant in the gauges and hoses that needs to be carefully released. Generally it is easier to release the refrigerant through the middle leg. Disconnect the middle hose at the plug connection and direct it into an empty can or other safe area. Slowly open each manifold valve, one at a time, until all the refrigerant has been released from the gauges.

There is a way to remove the gauges and avoid losing quite as much refrigerant. Leave the unit running. Instead of back-seating both service valves, back-seat only the discharge service valve. Crack open both manifold valves. This will allow the high-pressure gas in the discharge side of the manifold to pass into the low side of the refrigeration system. The pressure on the gauges will then be equal to the low-side operating pressure. This is the lowest pressure any part of the system will ever have on it. After the pressures in the gauge manifold have come down to the operating low-side pressure, back-seat the suction service valve. The pressure trapped in the gauges can now be bled

off through the middle hose, but now the trapped pressure is significantly lower.

SAFETY TIP

If an error or equipment failure causes an unexpected release of refrigerant, keep your hands and body out of the refrigerant spray. Do not try to replace a hose or valve cap on a valve that has refrigerant escaping. Liquid R-410a is approximately -60°F at atmospheric pressure. It does not take long to get a nasty frostbite burn at that temperature.

27.9 CONNECTING A GAUGE MANIFOLD SET TO SCHRADER VALVES

Schrader valves automatically open when a hose with a core depressor is connected to them. The service technician normally does not have control over when the valve opens and closes. When hoses are connected, the valve opens; when hoses are removed, the valve closes.

SERVICE TIP

Typically one end of a refrigeration hose is straight and the other end is angled to allow easier connection to service valves. The straight end connects to the manifold, and the angled end connects to the valves on the unit. Only the angled end contains a Schrader core depressor. When connecting to Schrader valves, the angled end must be connected to the valve to get a reading.

Frequently the valve will open before the seal is made and release refrigerant. If the Schrader valve is on the liquid line, the liquid that comes out will be extremely cold as it flashes off at atmospheric pressure. Occasionally the hose will seat before the core is depressed, and no pressure will be read. Some manufacturers' hoses have adjustable core depressors that can help either of these situations (Figure 27-21).

Figure 27-21 Adjustable core depressor.

SAFETY TIP

When servicing a system with R-410a, always use gauges designed for the higher pressures produced by R-410a systems. NEVER connect gauges designed for lower-pressure refrigerants to an R-410a system!

One way of minimizing the risk to the technician is to install the gauges on the Schrader valves with the system off. This reduces the pressures available at the high-side valve when the hose is connected and reduces the chance of liquid refrigerant escaping. Connecting with the system off also makes purging the gauges easier. The gauges may be purged by opening the valves one at a time and releasing the air through the center hose.

Tools are available that give the technician more control over the valve. With control over when the valves open and close, gauges may be safely connected to Schrader valves with the unit in operation. A valve-core-removal tool like the one shown in Figure 27-17 allows gauges to be connected before opening the valve. Then the tool is used to remove the core, opening the system to the gauges. This also has the advantage of improving flow through the valve. This type of core-removal tool can be used to change a Schrader valve core without recovering the system refrigerant.

A simpler tool, the thumbscrew core depressor, also allows the connection of gauges before the valve is opened (Figure 27-22). Turning in the thumbscrew depresses the valve core and opens the valve. This process is reversed to remove the gauges. The thumbscrew is turned out, allowing the valve to close. After the valve is closed, the gauges are removed.

27.10 REMOVING A GAUGE MANIFOLD SET FROM SCHRADER VALVES

When a hose is disconnected from a Schrader valve, the refrigerant that is trapped in the hose and gauges comes back out. This can be a surprising amount of refrigerant when the high side is connected to the liquid line. Positive-shutoff hoses can drastically reduce the amount

Figure 27-22 Thumbscrew core depressor valve. (Courtesy of Ritchie Engineering Company, Inc., Yellow Jacket Products Division)

Figure 27-23 Positive-shutoff adapters make connecting to Schrader valves easier.

of refrigerant released when the gauges are disconnected. Positive-shutoff devices include check valves on the end of refrigerant hoses, manually operated ball valves on the ends of hoses, and adapters that can be used with standard hoses. Available adapters include check valves, mechanisms like the quick couplings used on air hoses, and ball valves (Figure 27-23).

The check valves built into the end of a hose keep refrigerant from flowing backward out of the hose (Figure 27-24). Refrigerant will be trapped in the hoses after the gauges have been disconnected using a positive-shutoff valve. Most of the trapped refrigerant can be put back in the system if the proper removal procedure is followed.

Using a positive-shutoff hose, disconnect the high side with the unit still operating. Now crack both the gauge manifold valves to allow the trapped high-pressure refrigerant into the low side. Last, disconnect the low side with the unit still operating. The remaining amount of refrigerant in the hoses can be safely and legally vented. Note that the gauges must be purged when they are connected, or part of what is going back into the system will be air and contaminants.

Figure 27-24 The hoses at the top of the picture have a standard Schrader core depressors. The hoses on the bottom of the picture have automatic check valves built in that keep the refrigerant in the hose from coming back out when the hose is removed.

Three simple steps will reduce your exposure to refrigerant spray if positive-shutoff hoses or adapters are not used. First, wear gloves and safety glasses. It is always a good idea to wear gloves and safety glasses when handling refrigerant, but it is especially important when using Schrader valves. Disconnect the low side with the system operating because the low-side pressure is lower with the unit on. Turn the system off and let the system sit for several minutes before disconnecting the high side, because the high-side pressure is lower with the unit off.

27.11 SECURING REFRIGERANT SYSTEMS

Tragically, an increasing number of people have killed themselves by intentionally inhaling refrigerant, a practice called “huffing.” The victims are often teenagers looking for a quick thrill from a readily available substance. The “high” is from dizziness due to lack of oxygen and is certainly not worth risking your life. Although the refrigerant in most systems is considered nontoxic, it can still asphyxiate you if you breathe in too much. Since refrigerant is heavier than air, once a large quantity gets in your lungs, it can be difficult to displace, and you suffocate. The bottom line is people die.

Safety caps are available that restrict access to refrigerant using valves caps that require a special tool to remove. The idea is to limit access to the refrigerant to professionals servicing refrigeration systems. Figure 27-25 shows safety caps that are used to secure refrigeration access valves. They can only be removed using the tool shown in Figure 27-26.

CODE TIP

Both the 2009 International Mechanical Code (IMC) 1101.10 and the 2009 International Residential Code (IRC) M1411.6 require tamper-resistant valve caps on refrigerant access ports located outside.

Figure 27-25 Safety locking caps for refrigeration access valves.

Figure 27-26 This tool is required to remove the locking caps.

27.12 ACCESSING SEALED SYSTEMS

Most small appliances, such as refrigerators or window units, do not have any valves installed at the factory. Instead, the systems are evacuated and charged at the factory through process tubes. A process tube, or process stub, is a copper tube connected to the system for the sole purpose of evacuating and charging the unit at the factory. The process tubes can be on the compressor or on one of the system lines (Figure 27-27). After the system is evacuated and charged at the factory, the process tube is pinched off and brazed shut.

The only way to gain access to these refrigeration systems is to use a valve that pierces a hole in the tubing. It is better to avoid entering a sealed system unless it is absolutely necessary, because poking a hole in a sealed system can create problems. The technician could literally be installing a leak. Small systems sometimes only hold a few ounces, and putting gauges on them can remove enough refrigerant to make the system undercharged. It is definitely not a good idea to install piercing valves on small sealed systems just to perform a routine check. However,

Figure 27-27 Process tube on hermetic compressor.

when the refrigeration system must be accessed, a piercing valve or piercing pliers are required.

SAFETY TIP

You must wear eye protection and gloves anytime you access a refrigeration system. Liquid refrigerant accidentally released from a pressurized system can be at an extremely low temperature that can cause blindness and skin burns. Never position your face or head in a direct line with an access port as you are attaching or removing hoses.

27.13 PIERCING VALVES

One of the easiest devices available for sealed-system access is the saddle piercing valve, or tap-a-line. These piercing valves are clamped to the tubing and sealed by a bushing gasket, and then they pierce the tube with a tapered needle. Most contain some sort of shutoff control. The technician should keep in mind that these valves should be used to gain temporary access to a hermetically sealed system for checking system operating pressures or for pressurizing for leak testing. The piercing valve shown in Figure 27-28 allows quick access to system pressures to immediately start diagnosing the refrigeration problem.

SAFETY TIP

Before brazing a Schrader valve onto a existing refrigerant line, all of the refrigerant in the system must be recovered. Any refrigerant that is allowed to enter the torch flame will produce a noxious gas. Breathing this gas can be dangerous and could even cause lung damage. Remove the Schrader core before brazing to keep it from becoming damaged.

Bolt-on piercing valves are bolted on the line, then the piercing needle is run down to pierce the copper tubing (Figure 27-29). Refrigerant flows through the hole pierced by the needle to the service port on the valve.

Figure 27-28 Bolt-on piercing valve.

Figure 27-29 The needle pierces the copper tubing to gain access to the refrigeration system.

Bolt-on piercing valves should be removed once the source of the sealed-system malfunction has been located. The only way to do this is to recover the refrigerant from the system through the piecing valve. After the refrigerant has been recovered, a permanent valve may be brazed on. One way to do this is to install the piercing valve on a process tube. After the refrigerant is recovered, the process tube can be cut and a permanent valve brazed onto the process tube. Figure 27-30 shows Schrader valves made for field application.

(b)

Figure 27-30 (a) Pigtail-type Schrader valve; (b) Schrader valve replacement cores.

Figure 27-31 Steps in installing a braze-on piercing valve. Braze-on piercing valves can be used as both a means of gaining access to a sealed system as well as a permanent valve.

Figure 27-32 These piercing pliers can be used to gain access to sealed systems.

Braze-on piercing valves are available, such as the one in Figure 27-31. They function like a Schrader valve after the tubing is pierced. Braze-on piercing valves can be used for initial access and left on the system. One safety concern with braze-on piercing valves is that they are brazed on while the system is still under pressure. Brazing on a system with pressure still in it is generally considered unsafe. If the tubing is overheated, it can rupture, allowing refrigerant and oil under pressure to blast out unexpectedly. The oil spray can ignite and create a flamethrower effect.

Another tool for accessing sealed systems is a set of piercing pliers (Figure 27-32). These can pierce the tubing and allow temporary access for system diagnosis and refrigerant recovery. Since the pliers obviously must be removed, they can only be used if the technician plans to recover the system refrigerant.

After piercing the system and recovering the refrigerant, a Schrader valve can be installed. Schrader valves are available for field installation in a variety of forms as seen in Figure 27-30. The core should be removed from the valve before brazing to avoid melting the plastic seals.

UNIT 27—SUMMARY

Service valves are used to gain access to the refrigeration system. Type II and Type III systems all have service valves installed at the factory, and Type I systems have process tubes. Commercial refrigeration systems typically use manual stem service valves on the suction and discharge sides of the compressor and on the liquid receiver. The normal operating

position of a manual stem service valve is back-seated. In the back-seated position, the service port is closed. System pressures can be read in the back-seat cracked position, in which the valve is turned one-half turn off of the back-seated position. Schrader valves are similar to the valves on car tires and are found on most residential air-conditioning systems. Schrader valves automatically open when a hose with a core depressor is connected and close when the hose is removed.

Type I systems must be accessed using piercing valves. Bolt-on piercing valves should be used for system diagnosis and refrigerant recovery but should not be left on the system. Braze-on piercing valves can be used for access and may be left on the system. Care should be taken when installing a braze-on piercing valve because of the inherent danger of brazing on a system under pressure.

It is important to use gauges designed for the system refrigerant. Gauges are available in a high-pressure range suitable for R-410a and in a lower-pressure range suitable for everything else. Never use gauges designed for lower-pressure refrigerants on R-410a systems. Positive-shutoff hoses or adapters help technicians control the flow of refrigerant in and out of the gauges, especially when using Schrader valves. The saturation temperature of common refrigerants can be read on the gauges by looking at the colored scales.

WORK ORDERS

Service Ticket 2701

Customer Complaint: Air Conditioner Freezes Up

Equipment Type: Packaged Terminal Air Conditioner (PTAC) Using R-22 Refrigerant

A service technician for the Rest Easy Motel chain is asked to look at a PTAC in one of the rooms because it cools poorly and freezes over. Like most PTACs, this one has no service valves of any kind. The technician knows that the two most common causes of air-conditioning evaporators freezing over are poor airflow and refrigerant undercharge. The technician decides to check the airflow first. The air filter is missing and the evaporator is very dirty. This is most likely causing reduced airflow over the evaporator. After cleaning the coil, the unit airflow is noticeably improved and the evaporator no longer freezes. The technician elects not to install a piercing valve and keep the system sealed. Instead, the system operation is checked by examining the system amp draw, airflow, and temperature drop across the evaporator coil.

Service Ticket 2702

Customer Complaint: Unit Operates but Does Not Cool

Equipment Type: Packaged Terminal Air Conditioner (PTAC) Using R-22 Refrigerant

A service technician for the Rest Easy Motel chain is asked to look a PTAC in one of the rooms because it operates but does not cool. Like most PTACs, this one has no service valves of any kind. The system operation

is checked by examining the system amp draw, airflow, and temperature drop across the evaporator coil. The amp draw of the compressor is less than half of the normal RLA rating. The coil appears clean, the airflow is normal, but the supply air is the same temperature as the return air; no cooling is taking place. The technician decides to install a bolt-on piercing valve on the low-side process tube. The reading on the low side with the compressor operating is 150 psig. The technician believes the compressor is bad but decides to install a piercing valve on the high-side process tube to be certain. The pressure on the high side with the compressor operating is also 150 psig. The compressor is condemned, the system refrigerant is recovered, the bolt-on piercing valves are removed, Schrader valves are brazed in, a new compressor and liquid line filter are installed, the system is evacuated to 500 microns, and a charge is weighed in.

Service Ticket 2703

Customer Complaint: Unit Does Not Cool Adequately

Equipment Type: Commercial Refrigeration Unit on Walk-in Cooler with R-134a

A technician is called to look at a walk-in cooler whose capacity has noticeably declined. A check of the system pressures at the suction and discharge service valves reveals that the suction pressure is very low and the high-side pressure is just slightly low. Both the system superheat and subcooling are high. The technician looks for system restrictions and finds a sweating liquid-line filter drier. The technician determines that the filter drier is restricted and decides to change the filter drier but does not want to recover all of the refrigerant. Instead, the king valve is front-seated and the system is operated until the filter drier no longer sweats and the pressure on the line leaving the king valve is 0 psig. The technician turns off the unit and waits to make sure the pressure does not go above 0 psig. The old filter drier is replaced with a new filter drier, the system is evacuated from the suction service and king valves to 500 microns, the king valve is back-seated, and the system is returned to service.

Job: Check Oil for Acidity on Semihermetic Compressor

Equipment Type: Commercial Refrigeration System with Semihermetic Compressor

A-1 Refrigeration changed the compressor in a commercial refrigeration system last week. A technician is sent to collect a small oil sample and perform an oil acid test on the oil to see if the oil is contaminated. The technician does not want to recover all the system refrigerant but knows that the refrigerant pressure must be taken off of the compressor before opening the oil plug, so the technician decides to isolate the compressor using the

suction and discharge service valves. First the system is operated long enough to warm up the crankcase and boil out any residual refrigerant from the oil. The system is turned off and locked out. Then gauges are installed on the compressor and both the service valves are front-seated. The compressor is now isolated from the rest of the system. A recovery system is used to recover the small amount of refrigerant in the compressor. The crankcase plug is removed, a small oil sample taken, the plug replaced, and the oil is tested. The oil is clean, so the technician pulls a 500-micron vacuum on the compressor through the suction and discharge service valves. The service valves are back-seated and the system is put back in operation.

UNIT 27—REVIEW QUESTIONS

1. What is the term for slightly opening a valve?
2. List three precautions when handling a gauge manifold set.
3. What can technicians do to reduce refrigerant loss through Schrader valves when they are not being used?
4. Why is it not always a good idea to install a gauge set and check system pressure?

UNIT 28

Refrigerant Management and the EPA

OBJECTIVES

After completing this unit, you will be able to:

1. discuss the significance of the Montreal Protocol.
2. outline the major provisions of Title VI, section 608, of the 1990 Clean Air Act.
3. determine the EPA-specified recovery level for a given refrigerant and system.
4. discuss the requirements for EPA certification.
5. explain the different types of refrigerant recovery.
6. discuss proper refrigerant-recovery technique.
7. discuss the difference between recovered, recycled, and reclaimed refrigerant.

28.1 INTRODUCTION

Understanding the laws and regulations designed to reduce the environmental impact of refrigerants is now a crucial part of an air-conditioning technician's responsibility. Technicians must now pass a certification exam to demonstrate their understanding of these regulations before they are allowed to handle refrigerant. Reducing refrigerant emissions through good service practices, leak detection, and refrigerant recovery is a big part of any HVACR technician's job.

28.2 THE MONTREAL PROTOCOL

The problems of ozone depletion and global warming affect the whole earth's atmosphere and cannot be addressed by the unilateral action of one country. In 1985, the United Nations sponsored a treaty called the Vienna Convention for the Protection of the Ozone Layer seeking international cooperation to address concerns about ozone depletion. The participants agreed to study the problem, share information, and work toward a solution. In 1987, twenty-nine signatories to the Vienna Convention developed the Montreal Protocol, which established target dates for the phaseout of ozone-depleting substances. To date, 191 countries have signed the Montreal Protocol.

28.3 1990 CLEAN AIR ACT

The United States Congress passed an extensive revision to the Clean Air Act in 1990. The legislation addresses many aspects of air pollution and air quality, including stratospheric ozone depletion. The Clean Air Act is divided into six major sections, called titles. The last section, Title VI, covers Stratospheric Ozone Protection. There are eighteen sections in Title VI, each dealing with specific aspects of the effort to address ozone depletion. These sections are numbered by the title and section. Section 608 is the eighth section of Title VI.

The Clean Air Act establishes the goals to be achieved and sets target dates. It does not set forth specific practices

and procedures; those are left to the EPA to establish and enforce. The legislation gives the EPA the authority to regulate ozone-depleting chemicals and their replacements, including refrigerant. Currently, the maximum possible fine for violation of the Clean Air Act is \$37,500 per incident per day. Note that multiple violations can add up to a substantial amount of money.

28.4 SECTION 608

Section 608 of Title VI establishes regulations to reduce emissions of ozone-depleting substances from everything except motor vehicle air conditioners, which are covered in section 609. Residential air conditioning, commercial and industrial refrigeration, and even transport refrigeration are covered in section 608. Regulations in section 608 establish:

- A prohibition on venting ozone-depleting refrigerants
- Technician certification
- Restrictions on the sale of ozone-depleting refrigerants
- Reclaimed refrigerant standards
- Certification of recycling and recovery equipment
- Refrigerant recovery levels
- Repair of substantial leaks in equipment with a charge greater than 50 pounds
- Safe disposal of appliances containing ozone-depleting refrigerant
- Recordkeeping

28.5 VENTING PROHIBITION

Effective July 1, 1992, individuals are prohibited from knowingly venting ozone-depleting refrigerants into the atmosphere while maintaining, servicing, repairing, or disposing of air-conditioning or refrigeration equipment or appliances. Four types of releases are permitted under the prohibition:

1. "De minimus" quantities of refrigerant released in the course of making good-faith attempts to recapture and recycle or safely dispose of refrigerant. *De minimus* is

Latin for the minimum, or a little. There is no specific quantity set as *de minimus*. Instead, *de minimus* is defined as the amount released while following the manufacturer's instructions for the recovery device being used.

2. Refrigerants emitted in the course of normal operation of air-conditioning and refrigeration equipment. Normal operating releases would include releases due to mechanical purging and small leaks. However, EPA requires the repair of substantial leaks in large equipment.
3. Releases of CFCs or HCFCs that are not used as refrigerants. For instance, mixtures of nitrogen and R-22 that are used as holding charges or as leak test gases may be released, because in these cases, the ozone-depleting compound is not used as a refrigerant. However, a technician may not avoid recovering refrigerant by adding nitrogen to a charged system; before nitrogen is added, the system must be evacuated to the EPA-specified recovery level. Otherwise, the CFC or HCFC vented along with the nitrogen will be considered a refrigerant. Similarly, pure CFCs or HCFCs released from appliances will be presumed to be refrigerants, and their release will be considered a violation of the prohibition on venting.
4. Small releases of refrigerant that result from purging hoses or from connecting or disconnecting hoses to charge or service appliances will not be considered violations of the prohibition on venting. However, recovery and recycling equipment manufactured after November 15, 1993, must be equipped with low-loss fittings.

28.6 TECHNICIAN CERTIFICATION

Since November 14, 1994, anyone who performs maintenance, service, repair, or disposal that could be reasonably expected to release refrigerants into the atmosphere must be certified. Examples of actions that require certification include connecting gauges, adding or removing refrigerant, or opening a sealed refrigeration system. Technicians performing jobs that do not involve the refrigeration system, such as hanging ductwork or wiring units, are not required to be certified. Four types of certification have been developed to address different types of equipment:

- Type I, for servicing small appliances
- Type II, for servicing high-pressure and very-high-pressure appliances
- Type III, for servicing low-pressure appliances
- Universal, for servicing all types of appliances except motor vehicle air conditioners

Type I: Small Appliances

A small appliance is defined as a product that is fully manufactured, charged, and hermetically sealed in a factory with 5 lb or less of refrigerant. Examples of small appliances include domestic refrigerators and freezers, window air conditioners, packaged terminal air conditioners and heat pumps, dehumidifiers, under-the-counter ice makers, vending machines, and drinking water coolers. Technicians working on small appliances must have either Type I or universal certification.

Type II: High-Pressure Appliances

High-pressure appliances use an ozone-depleting refrigerant with a boiling point at atmospheric pressure between -58°F and 50°F . This category covers the widest of variety of appliances, including residential air conditioning, commercial air conditioning, commercial refrigeration, and transportation refrigeration.

Type II: Very-High-Pressure Appliances

Very-high-pressure appliances use an ozone-depleting refrigerant with a boiling point at atmospheric pressure below -58°F and are typically cryogenic scientific equipment operating at extremely low temperatures. These appliances represent a very small portion of the refrigeration industry.

Technicians working on either high-pressure or very-high-pressure appliances must have either Type II or universal certification.

Type III: Low-Pressure Appliances

Low-pressure appliances use an ozone-depleting refrigerant with a boiling point at atmospheric pressure above 50°F . The low-side pressure on these systems usually operates in a vacuum. Large chillers are the only common type of low-pressure systems. Technicians working on Type III low-pressure appliances must have either Type III or universal certification.

MVAC-like Appliances

An MVAC-like appliance is an air conditioner in a non-road vehicle, such as agricultural and construction vehicles. These systems are generally identical to those found in cars and trucks, but the vehicles do not operate on the public road system. A farm tractor with an air-conditioned cab is an example of an MVAC-like appliance (Figure 28-1). Technicians working on MVAC-like appliances may be certified under either section 608 or section 609.

Figure 28-1 Large agricultural machinery, like this cotton picker with an air-conditioned cab, is classified as an MVAC-like appliance. (Dmitry Kalinovskiy/Shutterstock.com)

Technician Certification Exam

To become certified, technicians are required to pass an EPA-approved test given by an EPA-approved certifying organization. There are four parts to the exam:

- Core
- Type I
- Type II
- Type III

Each section has twenty-five questions. Sections are scored individually, and each section is passed or failed as a section. Technicians must correctly answer eighteen questions to receive credit for a section and must pass the Core and at least one other section to become certified. The number of sections passed determines their certification, and a universal certification is issued to people who pass all four sections.

TECH TIP

Although universal certification implies that technicians are certified to work on anything, universal certification does not cover MVAC systems, motor vehicle air-conditioning systems. A section 609 certification is required to work on motor vehicle air-conditioning systems.

28.7 REFRIGERANT SALES RESTRICTION

Since November 14, 1994, the sale of refrigerant in a container of any size has been restricted to certified technicians. The sales restriction covers refrigerant containing parts as well as refrigerant in cylinders or drums.

What Is Not Covered

Fully assembled appliances containing refrigerant such as household refrigerators, window air conditioners, and packaged air conditioners are not included in the sales restriction. HFC refrigerants are also not covered. Uncertified people may purchase HFC refrigerant such as R-134a. Precharged split systems may also be purchased by uncertified individuals, providing all of the components are sold at one time. Components of precharged systems are still subject to the sales restriction if sold individually.

TECH TIP

While it is legal for uncertified individuals to purchase an entire precharged split system, they may not install the system. Connecting the refrigerant lines requires a certified technician.

28.8 RECOVER, RECYCLE, RECLAIM

Refrigerant that has been removed from a system contains impurities. What is done with refrigerant removed from a system depends upon the level of cleaning the refrigerant undergoes and whether the refrigerant will change ownership. The EPA uses three terms to describe the condition of refrigerant that has been removed from a system: recovered, recycled, and reclaimed. Although these terms all have a similar meaning in general use, they have very specific meanings when used to describe refrigerant in the context of EPA regulations.

Recovered Refrigerant

Recovered refrigerant has been removed in any condition from an appliance and stored in an external container without necessarily testing or processing it in any way. Recovered refrigerant may not change ownership; it may not be removed from one owner's system and then charged into a system owned by someone else. Recovered refrigerant may be charged into the system it came from or another system of the same owner.

Recycled Refrigerant

Recycled refrigerant has been removed from an appliance and cleaned for reuse without meeting all of the requirements for reclamation. In general, recycled refrigerant is refrigerant that is cleaned using oil separation and single or multiple passes through replaceable-core filter driers, which reduce moisture, acidity, and particulate matter. Although recycled refrigerant is safer than recovered refrigerant, it has the same basic restrictions. It may not be removed from one owner's system and then charged into a system owned by someone else. Recycled refrigerant may be charged into the system it came from or another system of the same owner.

Reclaimed Refrigerant

Reclaimed refrigerant has been reprocessed to at least the purity specified in AHRI Standard 700-2007, Specifications for Fluorocarbon Refrigerants. Its purity has been verified using the analytical methodology prescribed in the Standard. Refrigerant reclamation requires specialized machinery not available at a particular job site.

Reclaiming is done by an EPA-approved refrigerant reclaimer at a reprocessing facility. Recovered refrigerant is sent to either a general reclaimer or back to the refrigerant manufacturer for reclaiming. Reclaimed refrigerant may be used anywhere new refrigerant may be used, and it may change ownership.

28.9 RECOVERY EQUIPMENT CERTIFICATION

Refrigerant recovery and recycling equipment manufactured on or after November 15, 1993, must be tested by an EPA-approved testing organization to ensure that it meets EPA requirements. Third-party testing is not required for equipment manufactured before November 15, 1993.

Figure 28-2 Recovery equipment should be certified by AHRI or UL.

Currently, the EPA has approved both the Air-Conditioning, Heating and Refrigeration Institute (AHRI) and Underwriters Laboratories (UL) to certify recycling and recovery equipment. Certified equipment can be identified by a label reading, “This equipment has been certified by AHRI/UL to meet EPA’s minimum requirements for recycling and/or recovery equipment. . . .” (Figure 28-2). The intended use for the recovery equipment is listed at the end of this statement.

The standards vary depending on the size and type of air-conditioning or refrigeration equipment being serviced. Recovery equipment for use with Type I small appliances must be able to recover 90 percent of the refrigerant in the small appliance when the small appliance compressor is operating and 80 percent of the refrigerant in the small appliance when the compressor is not operating. Figure 28-3 shows the recovery levels for equipment intended for use with Type II air-conditioning and refrigeration systems. Recovery equipment for Type III, low-pressure systems, must be able to lower the pressure in the system to an absolute pressure of 25 mm of mercury. This is approximately 29 in of mercury vacuum.

Equipment Grandfathering

Equipment manufactured before November 15, 1993, including homemade equipment, may be grandfathered if it meets the standards shown in Figure 28-3.

Type of Appliance	Refrigerant Examples	Manufactured Before 11/15/1993	Manufactured on or After 11/15/1993
Very high pressure	R-13, R-503	0 psig	0 psig
R-22 < 200 lb	R-22	0 psig	0 psig
R-22 ≥ 200 lb	R-22	4 in Hg vacuum	10 in Hg vacuum
Other high pressure < 200 lb	R-12, R-502	4 in Hg vacuum	10 in Hg vacuum
Other high pressure ≥ 200 lb	R-12, R-502	4 in Hg vacuum	15 in Hg vacuum
Low-pressure appliance	R-11, R-123	25 in Hg vacuum	25 mm Hg absolute pressure

Figure 28-3 Type 2 and type 3 recovery levels.

Companies Must Own Refrigerant-Recovery Equipment

The EPA requires people servicing or disposing of air-conditioning and refrigeration equipment to certify to the appropriate EPA regional office that they have acquired recovery or recycling equipment and that they are complying with the applicable requirements of this rule. This certification must be signed by the owner of the recovery equipment or another responsible officer of the company and sent to the appropriate EPA regional office. Figure 28-4 shows a sample form. Although owners of recycling and recovery equipment are required to list the number of trucks based at their shops, they do not need to have a piece of recycling or recovery equipment for every truck. Owners do not have to send in a new form each time they add recycling or recovery equipment to their inventory.

28.10 FACTORS AFFECTING RECOVERY REQUIREMENTS

Technicians need to know when they have finished recovering the refrigerant from a system. Removing all the refrigerant would require evacuating the system until achieving a perfect vacuum of 29.92 in Hg. Fortunately, the EPA recognized that this would be impractical and in most cases impossible. The EPA uses the term *evacuate* when talking about the use of recovery equipment and the phrase “evacuate to the atmosphere” when describing the use of vacuum pumps. The recommended evacuation levels are based on the following factors.

The recovery levels for each of these specific circumstances are discussed in the following sections. Knowing these evacuation levels is extremely important; every section of the EPA certification exam will ask several questions about refrigerant evacuation (recovery) levels.

28.11 RECOVERY-LEVEL EXCEPTIONS

Two exceptions to the EPA-mandated recovery levels are permitted: opening systems for minor repairs and evacuating leaky systems.

Major and Minor Repairs

Systems can be opened for minor repairs after recovering the refrigerant to a level of 0 psig instead of the EPA-mandated evacuation level for that particular system. A minor repair is one that does not involve the compressor, condenser, evaporator, or auxiliary heat-exchange coil. Work on any of these

components is considered a major repair and requires the full EPA-mandated evacuation. An example of a minor repair would be replacing a filter or a valve in a refrigerant line.

SERVICE TIP

The practical usefulness of the minor repair exclusion is limited. The EPA does not allow the system to be evacuated to the atmosphere after performing the minor repair. This means that the technician is not allowed to pull a deep vacuum on the part of the system that was opened before placing the system back into service. It is poor refrigeration practice to open systems and not pull a vacuum on them afterward.

Leaky systems may also be evacuated to 0 psig instead of the EPA-mandated recovery level for the system. The system must be evacuated to the lowest practical level, but that level can be no higher than 0 psig. Trying to evacuate a system with a leak below 0 psig can result in sucking air into the system and mixing it with the recovered refrigerant.

28.12 RECOVERY MACHINES: OLD VERSUS NEW

The age of the recovery machine affects the required recovery level in most cases. Specifically, if the recovery equipment was manufactured before November 15, 1993, then the required evacuation levels are not as stringent as the vacuum levels required of machines made on or after November 15, 1993. Older recovery equipment is not required to have low-loss fittings, but equipment manufactured on or after November 15, 1993, must have low-loss fittings on the refrigerant hoses.

TECH TIP

The Clean Air Act was passed in 1990 and specified that it would take effect beginning in 1992. The law did not flesh out all the specific details involved in recovering refrigerant but simply said that it had to be done. Well, 1992 came and went, and the EPA had not completed work on the details, so there was no way to know exactly what would be required, other than the refrigerant could no longer be released to the atmosphere when installing, servicing, or disposing refrigeration equipment. So equipment manufacturers had to design, manufacture, and sell machines that could not possibly be built to any standard, since there was not a standard. These early machines were bulky, expensive, and generally not able to meet the standards that the EPA later published. In fairness to the contractors who purchased these early noncertified machines, the EPA published a less stringent set of recovery levels when they published their first set of regulations. This is why technicians now have two sets of refrigerant-recovery levels to memorize.

28.13 TYPE I EQUIPMENT-RECOVERY LEVELS

When using a recovery device manufactured before November 15, 1993, the recovery level for Type I systems is 80 percent, regardless of the appliance compressor condition. When using a recovery device manufactured on or after November 15, 1993, recovery levels for Type I systems are established based on the condition of their compressor.

- 90 percent for appliances with operational compressors
- 80 percent for appliances with nonoperational compressors

These recovery levels are valid for both system-dependent (passive) and self-contained (active) recovery devices. Self-contained recovery devices may also be certified by achieving a vacuum level of 4 in Hg.

SERVICE TIP

The Type I recovery requirements are unique because they specify what percentage of the system's refrigerant charge must be recovered instead of a vacuum level. The percentage charge that a recovery device can capture is tested using a very specific EPA-prescribed test stand following the device manufacturer's instructions. If the recovery device successfully recovers the desired amount of refrigerant on the EPA test device, it is assumed that the same device will perform similarly in the field when used according to the manufacturer's instructions. It is important to read and follow the instructions provided with the recovery device. Field technicians are not required to prove that they successfully recovered 80 percent of the system's charge; they only have to demonstrate that they followed instructions using an EPA-approved device.

28.14 TYPE II EQUIPMENT-RECOVERY LEVELS

Remembering Type II recovery levels can be quite a challenge, but there are a few organizational tricks that will help.

Very-High-Pressure Refrigerants

The recovery level for systems using a very-high-pressure refrigerant is 0 psig. Neither the age of the recovery machine nor the amount of refrigerant in the system has any effect on this level.

HCFC-22

The recovery level for systems that hold less than 200 lb of R-22 is 0 psig, regardless of when the recovery machine was manufactured. It is important to note that this means 200 lb by weight, not the pressure reading.

The recovery level for a system holding 200 lb or more of R-22 is established by when the recovery machine was

manufactured. The recovery level for machines made before November 15, 1993, is 4 in Hg vacuum. The recovery level for machines made on or after November 15, 1993, is 10 in Hg vacuum.

SERVICE TIP

There are very few systems that hold 200 lb of R-22. Typical residential systems hold less than 10 lb, and even 25-ton commercial systems only hold around 50 lb.

Other High-Pressure Refrigerants

High-pressure refrigerants other than R-22 require lower recovery levels than R-22. For systems holding less than 200 lb of refrigerant other than R-22, the recovery level is 4 in Hg vacuum when using a recovery machine made before November 15, 1993, and 10 in Hg vacuum when using a recovery machine made on or after November 15, 1993.

The final set of recovery levels is for systems using 200 lb or more of a high-pressure refrigerant other than R-22. The recovery level when using a recovery machine manufactured before November 15, 1993, is 4 in Hg vacuum. The recovery level when using a recovery machine manufactured on or after November 15, 1993, is 15 in Hg vacuum.

Old Recovery Machines

The recovery level for high-pressure refrigerants when using a recovery machine manufactured before November 15, 1993, is never more than 4 in Hg vacuum. This simplifies remembering the recovery level when using an older recovery machine. For very-high-pressure refrigerants and R-22 systems holding less than 200 lb of refrigerant, the recovery level is 0 psig. For every other high-pressure refrigerant situation, when using a recovery machine manufactured before November 15, 1993, the recovery level is 4 in Hg vacuum.

Decision Flow Chart

Figure 28-5 is a decision flow chart that helps organize Type II recovery levels.

28.15 TYPE III EQUIPMENT-RECOVERY LEVELS

Type III recovery levels are easy to remember: the target number is always 25. When using a recovery device that was manufactured before November 15, 1993, the required evacuation level is 25 in Hg vacuum. When using a recovery device manufactured on or after November 15, 1993, the required recovery level is 25 mm Hg absolute pressure. The amount of refrigerant in the system is irrelevant for Type III systems. An easy way to remember the evacuation levels for Type III low-pressure systems is to remember that inches is the old way to measure and millimeters is the new way.

Figure 28-5 Decision flow chart for Type II refrigerant-recovery levels.

TECH TIP

Although 25 in vacuum and 25 mm absolute look similar, they represent very different evacuation levels. Atmospheric pressure is normally about 29.92 in Hg. A vacuum level of 25 in Hg vacuum means that 25 of the original 29.92 inches have been removed, leaving an absolute pressure of about 4.92 in Hg. This method of establishing vacuum measures how much pressure has been removed from the system. The 25 mm absolute pressure required for newer recovery machines measures how much pressure remains after evacuating the system. Since 25 mm is approximately 1 in, a pressure of 25 mm absolute is roughly equivalent to 29 in Hg vacuum, about 1 in shy of a perfect vacuum.

28.16 SAFE DISPOSAL

Equipment that is typically dismantled onsite before disposal must have the refrigerant recovered in accordance with EPA's requirements for servicing before being dismantled. Examples of equipment requiring refrigerant recovery in the field before disposal include commercial refrigeration equipment, central residential air conditioning, chillers, and industrial process refrigeration. However, equipment that typically enters the waste stream with the charge intact, such as household refrigerators and room air conditioners, is subject to special safe-disposal requirements.

The final person in the disposal chain, such as the scrap metal recycler or landfill owner, is responsible for ensuring that refrigerant is recovered from the equipment before disposal. However, technicians “upstream” can remove the refrigerant and provide documentation to the final person if this is more cost effective. The final person in the disposal chain must have documentation showing who removed the refrigerant if he accepts appliances that no longer hold a refrigerant charge. The documentation must include a signed statement listing the name and address of the person who recovered the refrigerant and the date that the refrigerant was recovered.

The equipment used to recover refrigerant from appliances prior to final disposal must meet the same performance standards as equipment used for servicing, but it does not need to be tested by a laboratory. Technician certification is not required for individuals removing refrigerant from appliances in the waste stream.

28.17 RECORD KEEPING

Technicians, service companies, equipment owners, wholesalers, and refrigerant reclaimers are all required to keep some form of documentation. Technicians must keep proof of their certification (Figure 28-6). Employers are also

Figure 28-6 EPA certification card.

required to keep copies of their employee’s certification. Technicians servicing appliances that contain 50 lb or more of refrigerant must provide the equipment owner with an invoice that indicates the amount of refrigerant added to the appliance. Owners of equipment that contains 50 lb or more of refrigerant must keep servicing records documenting the date and type of service, as well as the quantity of refrigerant added (Figure 28-7). Owners of equipment that contains less than 50 lb of refrigerant are not required to keep records of refrigerant use. Wholesalers who sell CFC and HCFC refrigerants must retain invoices that indicate the name of the purchaser, the date of sale, and the quantity of refrigerant purchased. Reclaimers must maintain records of the names and addresses of people sending them material for reclamation and the quantity of material sent to them for reclamation.

28.18 HAZARDOUS WASTE

Recycled or reclaimed refrigerants are not considered hazardous under federal law. Used oils contaminated with CFCs are not treated as hazardous on the condition that the oil:

- Is not mixed with other waste
- Has been subjected to CFC recycling or reclamation
- Is not mixed with used oils from other sources

28.19 RECOVERY EQUIPMENT

Recovery equipment is classified as either system dependent or self-contained. System-dependent recovery equipment depends on the system from which the refrigerant is being recovered to help remove the refrigerant. Self-contained recovery equipment does not rely on the system because the recovery equipment has its own means of moving the refrigerant, typically a compressor.

Figure 28-7 A refrigerant data log is used to document the amount of refrigerant added to systems containing 50 lb or more of refrigerant.

System-Dependent Recovery Devices

System-dependent recovery devices may be used for recovering refrigerant from systems containing up to 15 lb of refrigerant. A system-dependent recovery device depends on the system from which the refrigerant is being recovered to help move the refrigerant. The most common system-dependent recovery device is basically a big plastic bag. As refrigerant enters it, its volume expands so that the pressure in the bag does not rise above 0 psig. The EPA refers to these bags as nonpressurized containers.

Whirlpool developed the bags for use with refrigerators. These bags will only hold about 1 lb of refrigerant. To use the bag on a refrigerator with an operating compressor, use the following steps:

- Connect the bag to the high side of the system.
- Let the refrigerant flow into the bag with the unit off for approximately 15 min.
- Start the compressor and let it operate for another 5 min.
- Remove the bag and cap it.

Figure 28-8 shows the correct connection for an appliance with an operational compressor.

To use the bag on a refrigerator with a compressor that will not operate:

- Connect the bag to BOTH the high side and low side of the system.
- Let the refrigerant flow into the bag with the unit off for approximately 15 min.
- Hit the compressor three times. (You read it right: *hit the compressor.*)

Figure 28-8 Connection of a system-dependent recovery device to a small appliance with an operational compressor.

- Heat the compressor with a hair dryer or heat gun for another 12 min.
- Remove the bag and cap it.

Figure 28-9 shows the correct connection for an appliance with a nonoperational compressor.

A vacuum pump can also be used with a nonpressurized container (bag). Connect the vacuum pump to both sides of the system and connect the discharge of the vacuum pump to the bag. This requires some ingenuity, because the vacuum pump is not designed to have its outlet connected to anything. The vacuum pump will pull the refrigerant out of the system and place it in the bag. Figure 28-10 shows the use of a vacuum pump and bag on an appliance with a nonoperational compressor.

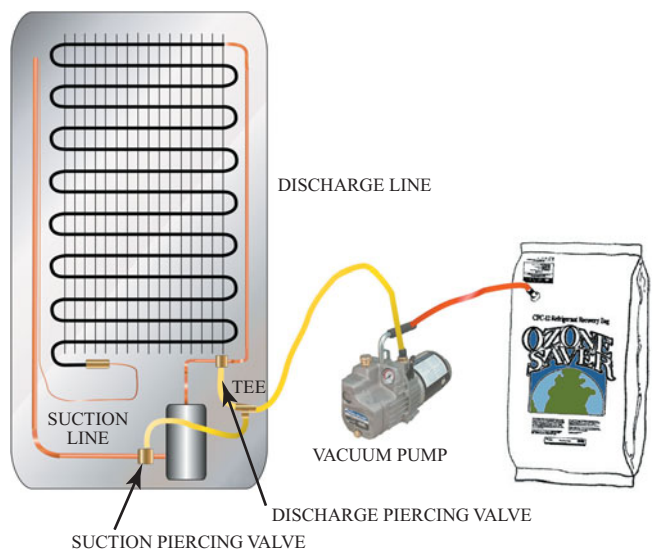

Figure 28-10 Connection of a system-dependent recovery device using a vacuum pump.

Figure 28-11 Self-contained recovery devices.

Self-Contained Recovery Devices

Self-contained recovery devices do not rely on the system the refrigerant is being recovered from for their operation. They typically are small, specialized condensing units (Figure 28-11). They have a compressor, a condenser, and valves that are used to control the refrigerant flow in and out of the recovery machine (Figure 28-12). Most modern self-contained recovery machines use oil-less compressors to reduce cross-contamination between refrigerants when changing from one refrigerant to another. Many also have purge cycles that will pump the refrigerant trapped in their condenser into the recovery cylinder after recovering the system refrigerant. A small amount of refrigerant is left between the outlet of the compressor and the outlet of the recovery machine. It is not a violation to release this small quantity of refrigerant to recover another type of refrigerant.

Figure 28-13 A standard hose end, shown on top, compared to a check valve hose end, shown on bottom.

Water-Cooled Recovery Machines

A very few recovery machines are water cooled. The water source for water-cooled recovery machines is city water (tap water).

28.20 LOW-LOSS FITTINGS

Low-loss fittings reduce the amount of refrigerant released when hoses are connected and disconnected by keeping refrigerant from leaving the hose when it is disconnected. The majority of the refrigerant released when disconnecting a hose from a Schrader valve is actually coming out of the hose, not the valve. This can be a significant amount of refrigerant when the hose is filled with liquid. All hoses used with recovery equipment built after November 15, 1993, are required to have low-loss fittings. These can be automatically closing check valves, like the one in Figure 28-13, or they can be manually controlled valves, like the one shown in Figure 28-14.

28.21 RECOVERY CYLINDERS

Nonrefillable cylinders should not be used for refrigerant recovery. Recovery cylinders are normally available in water capacities of 27 and 47 lb. Refillable and recovery cylinders

Figure 28-14 Short hose sections with manual shutoff valves.

Figure 28-15 Refrigerant-recovery cylinder.

are regulated by the DOT in Code of Federal Regulations 49, covering the transport of hazardous materials. Figure 28-15 shows a typical refrigerant recovery cylinder.

Cylinder Markings

Cylinders are marked with the particular DOT specifications for that cylinder (Figure 28-16). Some crucial cylinder markings are the following:

- DOT specification
- Water capacity
- Tare weight
- Date of manufacture
- First retest date
- Most recent test date
- Last allowable retest date

The numbers and letters immediately following the letters DOT describe how the cylinder is made, while the last group of numbers describes the cylinder service pressure. For example, a DOT-4BA-350 recovery cylinder is a welded or brazed steel cylinder with a recommended service pressure of 350 psig (Figure 28-17). This is the most common specification for refrigerant-recovery cylinders. DOT 4BA-400 cylinders are used for refrigerant R-410A recovery because of its high pressures. These cylinders have recommended service pressures of 400 psig.

The water capacity is the weight of the water to completely fill the cylinder (Figure 28-18). The tare weight is the

Figure 28-16 The cylinder specifications are stamped into the collar of the cylinder.

Figure 28-17 This cylinder has a service pressure of 350 psig.

Figure 28-18 The weight of the water to completely fill this cylinder is 47.6 lb.

Figure 28-19 This cylinder weighs 28.1 lb empty.

weight of the empty cylinder (Figure 28-19). The tare weight and water capacity are used to calculate how much refrigerant the cylinder can safely hold.

Cylinders with a service pressure under 300 psig must be tested every ten years. Cylinders with a service pressure of 300 psig or more must be tested every five years. The date of manufacture and the first retest date are on every cylinder (Figure 28-20). The first retest date gives the month and year that a cylinder must be requalified. If the first requalification date has not yet arrived, the cylinder should still be on its first five years. Note that the five years starts when the cylinder is made, not when it is purchased. A cylinder that was made two years ago can only be used for another three years before getting requalified, even if it has been sitting on the shelf in the store. If the first retest date has already passed, the cylinder should not be used

Figure 28-20 This cylinder was manufactured in July 1998.

Figure 28-21 The last date that this cylinder may be used is 10 years after its date of manufacture.

unless it was retested. If it was retested, the date that it was retested should be stamped on the cylinder. If the date was less than five years ago, the cylinder should be safe to use.

Some cylinders also have a last permissible use date. These are commonly known as 5 + 5 cylinders. They can only be requalified one time. These cylinders may not be used past the last permissible use date (Figure 28-21).

Cylinder Color

AHRI Guideline K specifies that recovery cylinders all be painted gray with a yellow top regardless of the type of refrigerant in the cylinder (Figure 28-25). Of course, these cylinders must be labeled with the type of refrigerant they contain, since cylinder color cannot be relied upon to identify them. The only thing the technician knows for sure by the color is that refrigerant in a gray and yellow cylinder is not new.

Pressure-Relief Valve

Recovery cylinders have an automatic pressure-relief valve built in that opens at 150 percent of the rated cylinder service pressure (Figure 28-22). The outlet of the relief valve should

Figure 28-22 Recovery cylinder pressure-relief valve.

never be plugged or obstructed by anything. These valves reset once the pressure in the cylinder has dropped to a safe level.

28.22 CYLINDER FILL LEVEL

Cylinders should never be filled more than 80 percent full of liquid by volume, and they should not be stored or used in temperatures exceeding 125°F. All refrigerant cylinders have a maximum recommended service pressure. Do not pressurize recovery cylinders above their rated service pressure.

However, do not rely on pressure to determine the safe fill level. It is possible to fill a cylinder completely up with liquid and remain below the cylinder service pressure. Remember that for saturated mixtures of liquid and gas, the pressure is established by the refrigerant temperature, not the amount of refrigerant in the cylinder. It does not matter if the cylinder is 25 percent full or 95 percent full; the pressure will be the same as long as the temperature is the same. In practice, the cylinder pressure gradually rises as recovery proceeds. This is because the warm refrigerant leaving the recovery machine tends to heat up the cylinder and all the refrigerant in it, raising the cylinder temperature and pressure. If the cylinder is cooled, its pressure will drop. Pressure absolutely cannot be relied upon to tell when a cylinder is full. Most recovery machines have high-pressure safety switches. Remember these are safety switches, not fill-level detectors. In short, do not simply fill the cylinder up until the high-pressure safety device shuts off the recovery machine! Remember that when a safety shuts something off, it generally indicates that there is a problem.

Observing the weight of the cylinder is the most commonly used method for determining when a cylinder is full. All DOT-approved cylinders have their tare weight and water capacity stamped on them. If a cylinder were refilled with water, the maximum safe fill level could be determined by taking 80 percent of the water capacity and adding it to the tare weight. Before blends, all commonly used refrigerants were denser than water. Most of the 400 series refrigerants

are less dense, and cylinders cannot safely hold as much of these refrigerants. In general, a cylinder will only hold 75–80 percent as much 400 series refrigerant in the same size cylinder as the older refrigerants used. For example, 30-lb disposable cylinders have been common for years. All refrigerants in them come in the same size cylinders with the same net weight. This does not mean that all these different refrigerants filled the cylinders up equally, but none of them overfilled the cylinders at this level. The familiar 30-lb cylinder can safely hold only 25 lb of R-410a refrigerant. The cylinder is 80 percent full by volume, but it weighs less because the refrigerant is less dense than the older refrigerants. Therefore, it is necessary to calculate the net weight for each specific type of refrigerant to know exactly how much refrigerant a recovery cylinder can safely hold. The formula is

$$\text{tare weight} + (0.8 \times \text{water capacity} \times \text{specific gravity of the refrigerant at } 77^\circ \text{ F})$$

- Tare weight is the weight of the empty cylinder. It is usually stamped as Tare or TW on the cylinder.
- Water capacity, stamped WC, is what the water would weigh if the cylinder were completely filled with water.
- The specific gravity of the refrigerant compares the weight of the refrigerant to the weight of water. This number must be looked up for each refrigerant.

Most refrigerant manufacturers do not give a specific gravity but list the refrigerant's density instead. To calculate the specific gravity, divide the refrigerant saturated liquid density at 77°F by 62.4, the density of water. The formula using the refrigerant density instead of specific gravity is

$$\text{tare weight} + (0.8 \times \text{water capacity} \times (\text{refrigerant density}/62.4))$$

Of course, this only has to be calculated one time for each cylinder. Figure 28-23 gives the safe fill level for the two most common sizes of recovery cylinders for several refrigerants.

Refrigerant	Density @77°	Specific Gravity @77°	11.9 WC 80% Fill	26.1 WC 80% Fill	47.6 WC 80% Fill

Figure 28-23 Safe fill level for common refrigerants and cylinder capacities.

Figure 28-24 Some recovery cylinders have a float that shuts off the recovery unit when the cylinder is 80 percent full.

Some recovery machines use float switches that cut the recovery machine off when the cylinder is 80 percent full (Figure 28-24). Others use temperature-sensing devices that sense the liquid level in the cylinder. Both of these are good safety devices, but they should not be used to determine fill level. Floats and switches are mechanical devices and can fail. It is important to always have a good idea how much room is in the cylinder and how much refrigerant will be recovered before starting.

28.23 RECOVERY TECHNIQUES

Remembering a few simple ideas will speed up refrigerant recovery.

- If possible, operate the system before beginning refrigerant recovery.
- Use the large-diameter, short-length hoses.
- Recover liquid first.
- Begin recovery at the lowest available access point.
- Heat the system from which refrigerant is being recovered.
- Cool the cylinder the refrigerant is going into.
- Recover from both sides of the system during vapor recovery.

Operate the System

If possible, operate the system before beginning refrigerant recovery. Refrigerant settles into the oil in the compressor. It takes a long time for recovery machines to vaporize this refrigerant out of the oil. Operating the compressor will pull the refrigerant out of the oil quicker.

Minimize Resistance Through Hoses and Connections

Short, large-diameter connection hoses will reduce the restriction that the recovery equipment must pull the refrigerant through. Reducing the restriction will increase the speed of recovery and decrease the time required to recover the refrigerant.

Recover Liquid First

Remove as much liquid from the system as possible before proceeding with vapor recovery. Liquid recovery is faster than vapor recovery because a pound of vapor takes up hundreds of times more space than a pound of liquid. Vapor recovery requires the liquid to vaporize, dropping its temperature and pressure. Liquid is removed either from the king valve on the liquid receiver or from the liquid service valve at the end of the condenser.

Let Gravity Help

When working on a system that has a difference in height between components, try to start your recovery at the lowest available access point. Rather than trying to pull liquid uphill against gravity, let gravity push the liquid down. For example, liquid recovery is normally done from the king valve on the liquid receiver, but when the condensing unit is located above the evaporator, liquid recovery should start at the liquid line at the evaporator instead (Figure 28-25). Similarly, if the receiver is located above the condenser, start liquid recovery at the outlet of the condenser (Figure 28-26).

Heat the System

One of the basic principles behind the refrigeration cycle is that pressure and temperature move up and down together. Heating the system both before and during recovery will increase the refrigerant pressure, and the refrigerant

Figure 28-25 Begin recovery at the liquid line entering the evaporator when the condenser is located above the evaporator.

Figure 28-26 Begin recovery at the outlet of the condenser when the condenser is located below the receiver.

Figure 28-27 The frost line on this accumulator indicates there is still liquid sitting in the bottom.

will come out faster. Pay particular attention to spots where liquid can puddle, such as the compressor, liquid receiver, filter driers, and accumulator (Figure 28-27). To prevent excessive pressures, the system should not be heated with torches or steam but with warm air or water.

Cool the Cylinder

The refrigerant-recovery cylinder should be cooled in addition to heating the system. Cooling the cylinder will decrease its pressure and speed the recovery process. Cylinders can be cooled with ice or chemicals or by active cooling (Figure 28-28). Active cooling involves connecting the recovery machine inlet to the vapor port on the cylinder and connecting the recovery machine outlet to the liquid valve on

Figure 28-28 Cooling the recovery cylinder in ice can speed system recovery by keeping the cylinder pressure low.

Figure 28-29 Recovery unit connected to cylinder to perform active cooling on the cylinder.

the cylinder (Figure 28-29). This turns the cylinder into an evaporator, cooling off the liquid and dropping its pressure. Some recovery units have this ability built in. They always connect to the cylinder with two hoses instead of one.

Recovering from Both Sides of the System

Vapor recovery is required to completely evacuate a system down to the EPA-specified level. The recovery machine should be recovering from both sides of the system simultaneously during vapor recovery (Figure 28-30). Attempting vapor recovery through just one port requires some of the gas to travel through either the metering device or the compressor, drastically increasing the time required.

Wait Before Opening the System

After recovering refrigerant to the required level, wait to be sure that the pressure in the system does not rise above the prescribed level. Any refrigerant that is pooled up in pockets, such as in the compressor crankcase, receiver, filter drier, or traps, will vaporize and raise the pressure in the

Figure 28-30 Recovery from both sides of the system when performing vapor refrigerant recovery.

system as it heats up. Heating the system at these locations can help combat this. It generally saves time to evacuate beyond the required level, because a slight pressure rise is almost guaranteed.

28.24 TYPE I REFRIGERANT RECOVERY

Some recovery techniques are unique to Type I appliances. Most Type I appliances do not have any type of service valves. The technician will have to add some type of service aperture before any refrigerant can be recovered. The EPA requires all Type I appliances to have a process stub or other “equally effective service aperture.” That is what most Type I systems have: a short piece of copper tubing that has been pinched closed on the end and brazed up (Figure 28-31). The only way this can be used is to pierce

Figure 28-31 Process stub on a compressor.

Figure 28-32 Bolt-on piercing valve installed on a system.

it with a piercing valve or piercing pliers. Bolt-on valves are more convenient and are relatively easy to use, but they frequently leak (Figure 28-32). They should not be left on the system for permanent access because of the relatively high probability of future leaks. Braze-on piercing valves are brazed to the line prior to piercing the tubing and are therefore less likely to leak. They can be used for both recovery and permanent access. However, using braze-on piercing valves raises a safety issue. Most equipment manufacturers caution against brazing on a system under pressure, but that is exactly what must be done to install a braze-on piercing valve. Another option for gaining system access is to use a set of piercing pliers. Piercing pliers allow refrigerant recovery from Type I appliances without leaving a valve on the system.

Schrader valves work for permanent access valves but can only be installed on a system that has already been evacuated (Figure 28-33). You should always check Schrader valves for leaks when working on systems using Schrader valves and replace leaky cores when necessary. Replace the valve caps after completing work on the system to avoid leaks.

Refrigerants that Should Not Be Recovered

Always check an appliance’s data plate for the type and amount of refrigerant before beginning recovery. This is especially true for small appliances. Some refrigerators built before 1950 contain poisonous chemicals, such as sulfur dioxide, methyl chloride, and ammonia. None of these noxious chemicals are covered under the refrigerant-recovery rules. However, for safety reasons, they should not be casually released to the air. Refer these systems to someone who is trained in handling them.

28.25 TYPE II REFRIGERANT RECOVERY

Type II systems cover the widest variety of applications, so the recovery techniques and equipment used for different Type II applications also varies widely. However, the order

Figure 28-33 Schrader access valve on process stub of small appliance.

of preference for speed of recovery from a Type II system is usually as follows:

- Recover into the receiver, also known as pumping a system down
- Push-pull
- Liquid recovery
- Vapor recovery

Recover into the Receiver

On systems with liquid receivers and king valves, time can be saved by pumping the system down into the receiver using the system compressor. Although the EPA uses the phrase “recover the refrigerant into the receiver,” this is more commonly known as “pumping the system down” in the field. Pumping all of the refrigerant into the receiver traps it between the discharge valve on the compressor and the king valve on the receiver (Figure 28-34). This is accomplished by front-seating the king valve and operating the system until the pressure on the low side of the system is at the EPA-required recovery level (Figure 28-35). It is much faster to move the refrigerant into the receiver or the condenser than it is to recover all of it. Pumping a system down is only an option if the system compressor operates and the part of the system to be serviced is on the low side of the system or on the liquid line after the king valve. It will not work for repairing anything between the compressor discharge valve and the liquid receiver king valve.

Many systems that do not have receivers can still be pumped down. Most air-conditioning systems have liquid-

Figure 28-34 All the refrigerant is trapped between the compressor discharge valve and the king valve when the system is pumped down.

Figure 28-35 Front-seating the king valve keeps refrigerants from leaving the liquid receiver.

line service valves and condensers large enough to hold an entire system charge (Figure 28-36). Residential air conditioners are normally shipped with an entire system charge trapped in the condenser. However, if the system has lines over 50 ft, or if it has been overcharged, the condenser may not hold the entire system charge. The compressor discharge pressure should be monitored while pumping down a system. It will become very high if the condenser fills with liquid and there is no more room for vapor. This can cause loud noises from inside the compressor when the internal pressure-relief valve opens.

Push-Pull Recovery

Many recovery-machine manufacturers rate the maximum speed of their recovery unit using the push-pull recovery

Figure 28-36 The liquid-line service valve on residential split systems can be used to pump the system down.

method. The push-pull recovery method pushes the gas discharged from the recovery machine into one part of the refrigerant system while pulling liquid out of the system.

In push-pull mode, either the liquid-line service valve or the king valve is connected to the liquid valve on the recovery cylinder. The vapor valve on the recovery cylinder is connected to the suction side, or inlet, of the recovery machine. The discharge, or outlet, of the recovery machine is connected to the discharge service valve on the compressor. Figure 28-37 shows the correct connections for push-pull liquid refrigerant recovery.

When the recovery machine runs, it will pressurize the condenser by pushing gas into it. The pressure of the recovery cylinder will be reduced because the recovery machine is pulling gas from it. At the same time, pulling gas off of the recovery cylinder forces some of the liquid in the cylinder to

boil. This reduces its temperature and pressure. The result is an increased pressure difference between the system and the recovery cylinder. This produces the fastest rate of recovery because the liquid leaves the refrigeration system quickly without having to boil. Not having to boil the liquid in the system keeps the system temperature and pressure higher, helping to maintain the high pressure difference.

One limitation of the push-pull setup is that all the system charge cannot be recovered this way. After recovering liquid, the recovery machine will have to be reconnected to finish by recovering vapor.

Liquid Recovery Without Push-Pull

Push-pull works well for systems with large amounts of liquid sitting in a receiver. However, it is much less effective with smaller residential air-conditioning equipment and heat pumps.

Most recovery units today have a setting for recovering liquid directly. They do this by having a built-in restriction that acts like a metering device to flash off the liquid before it reaches the recovery unit's compressor. This setting can be used to start the recovery process with liquid and switch over to vapor without moving hoses.

First, check the weight of the recovery cylinder to make sure it has room for the refrigerant in the system. Use the procedure outlined in section 28.22, Cylinder Fill Level, to determine the total weight of the cylinder and refrigerant when filled to the maximum safe fill level of 80 percent. Weigh the cylinder. Subtract the actual cylinder weight from the maximum safe fill-level weight; the difference is the amount of room in the cylinder, which should exceed the amount of charge listed on the equipment data plate.

Figure 28-38 shows a typical setup for recovering liquid refrigerant from a residential split system. The gauges are connected as they normally are, with the high-side manifold

Figure 28-37 Liquid recovery using the push-pull method.

hose connected to the liquid-line service valve and the low-side manifold hose connected to the suction service valve. The center manifold hose connects to the inlet of the recovery unit, and the outlet of the recovery unit connects to the vapor port on the recovery cylinder.

All hoses should be purged of air before proceeding with recovery. The high-side manifold gauge valve should be opened, the recovery inlet valve set for liquid recovery, the recovery outlet valve opened, and the refrigerant cylinder vapor valve opened (Figure 28-39). Operate the recovery unit and watch the pressures in the system and on the recovery unit gauges. An operating recovery system should not be left unattended. Most of the liquid will have been removed when the system pressure is substantially less than the saturation pressure corresponding to the system temperature. The gauges and hose connections will feel cold as liquid flashes off coming through them. When all the liquid has been recovered, those parts that were cold will begin to warm up. After all the liquid has been removed, switch to vapor recovery to finish.

Vapor Refrigerant Recovery

To switch from direct liquid recovery to vapor, put the recovery inlet valve to vapor (Figure 28-40). This lets the vapor flow into the recovery unit unrestricted and speeds vapor recovery. Open both manifold valves so that the recovery unit pulls from both sides of the system. Any remaining cold pockets in the system should be heated using a heat gun. Monitor the system pressures and let the recovery go a little past the EPA-mandated recovery level. For example, if the system holds less than 200 lb of R-22, the recovery level is 0 psig. Recover down to 5–10 in Hg vacuum instead of stopping at 0 psig. After achieving a vacuum slightly lower than the target vacuum, close the manifold valves and shut off the recovery machine (Figure 28-41). Wait to see if the system pressures are going to stay under the EPA-mandated level. It is normal for the pressure in the system to rise a little; that is why it is a good idea to recover past the required level. If the system pressure is stable and at or below the EPA-mandated level, the recovery is complete. Put the

Figure 28-41 Recovering to 5 in Hg vacuum will help ensure that the system pressure will stay at or below 0 psig when the recovery unit is shut off.

recovery-machine valves in the purge position and operate the recovery machine until it has moved the refrigerant trapped in it into the recovery cylinder (Figure 28-42). This normally only takes a few minutes. Close all valves before breaking down the recovery setup.

28.26 VERY-HIGH-PRESSURE RECOVERY

Very-high-pressure refrigerants have saturated pressures in a range of 250–700 psig at room temperature. They are used in low-temperature systems and cascade systems. Cascade systems are actually a combination of two refrigeration cycles. The evaporator of one is used to cool the condenser of the other. The system operating at the highest temperatures uses a “normal” high-pressure refrigerant such as R-404A. The system with the ultra-low evaporator temperature uses a very-high-pressure refrigerant, such as R-508. Technicians should be aware of which system they are recovering from when working on cascade systems. A

Figure 28-42 The recovery unit valves are positioned to purge its condenser of refrigerant.

recovery system that is certified for R-404A is not suitable for recovering R-508.

Recovery machines and cylinders for very-high-pressure refrigerants are designed for the extreme pressures of these refrigerants. Never use a recovery machine that is not specifically designed for very-high-pressure refrigerant. It is a violation of EPA regulations to use a recovery unit that is not AHRI/UL certified for the type of refrigerant being serviced. Figure 28-43 shows a recovery unit specifically certified for very high pressure refrigerant.

SAFETY TIP

Always check the AHRI/UL rating on the recovery device before using it, especially with very-high-pressure refrigerants. Using a “standard” recovery unit on a system with very-high-pressure refrigerant is extremely dangerous because the components in the device are not designed to withstand the extreme pressures of very-high-pressure refrigerant.

28.27 CHILLERS AND WATER-COOLED SYSTEMS

Recovering vapor from a system that still has liquid refrigerant in it forces the liquid to boil to replace the vapor. The liquid temperature and pressure drop as a result. Recovering vapor refrigerant from water-cooled systems or chillers can drop the temperature and pressure of the refrigerant to the point that water in the chiller tubes or condenser shells begins to freeze. Freezing the water in tubes or shells can cause extensive damage to the system when the ice expands. Always recover liquid first from any system with water in either side to prevent damaging the system! Liquid does not have to boil to make vapor during liquid recovery, so the system pressure and temperature will not drop as rapidly. Another trick is to circulate the water while recovering the refrigerant. Running water is far less likely to freeze. It is possible to remove all the water from small systems, but this is normally not practical in larger systems.

28.28 TYPE III REFRIGERANT RECOVERY

The vast majority of Type III systems are chillers, so the procedures in the previous section on chillers also apply to these systems.

Evaporator Operates in Vacuum

The fact that the evaporator on a low-pressure chiller operates in a vacuum presents some unique problems. The recovery levels for low-pressure systems are very low: 25 in Hg of vacuum for recovery machines built before November 15, 1993, and 25 mm absolute pressure for recovery machines built on or after November 15, 1993.

Purge Unit

All low-pressure systems have purge units. These units purge the system of air that sucks into the low side during system operation because of system leaks in the low side. Air sucks in rather than refrigerant leaking out because the air pressure in the room exceeds the pressure in the evaporator, which is in a vacuum. Since air is a noncondensable, it travels to the condenser and stops there. A buildup of noncondensables increases the system high-side pressure and reduces its efficiency. A purge unit gets rid of the gas at the top of the condenser where noncondensables collect. The purge unit on a system that is relatively leak free will not operate very much because noncondensables are not

collecting in the system. On the other hand, a leaky system will have a lot of purge operation because noncondensables will constantly be entering the system through the leaks on the low side.

Minor Repair Exclusion

The minor repair exclusion can be used with low-pressure systems. However, instead of recovering refrigerant to reach 0 psig, the low-side pressure must be raised to 0 psig before opening the system for service for a minor repair, since the low side is normally in a vacuum.

Raising the Low-Side Pressure

One common low-pressure refrigerant, CFC-11, has a boiling point of 75°F. This means that the system pressure will be below 0 psig anytime the system temperature is below 75°F. If the low side of a low-pressure system is opened, it will suck in air. This will lead to increased purge operation when the system is put back into operation. Purge operation should be minimized since some refrigerant is always lost when operating the purge unit.

There are two common methods used for raising the pressure of the evaporator on a low-pressure chiller: adding nitrogen until the pressure comes up to 0 psig or circulating warm water through the chiller tubes. Adding nitrogen is better for the system than letting a bunch of air suck in because the air will contain oxygen and water as well as nitrogen. Since both these contaminants can harm the system, they are to be avoided. However, adding nitrogen is discouraged by the EPA because it increases the purge operation and increased purge operation amounts to increased refrigerant release. The EPA endorses circulating warm water through the chiller bundle to raise the evaporator pressure. The increase in temperature will cause a corresponding increase in pressure in the chiller.

SAFETY TIP

Be careful while circulating water in low-pressure chillers! The heat from the pump motors can heat the refrigerant in the chiller enough to build pressures over 15 psig, the point where the rupture disk opens. All the system refrigerant can be lost if the rupture disk breaks. This is an expensive accident for a system that holds thousands of dollars worth of refrigerant.

Rupture Disk

All low-pressure chillers have a rupture disk on the evaporator that opens at 15 psig and vents all the refrigerant out of the evaporator (Figure 28-44). This is a physical safety device that literally breaks, meaning that there is no putting the genie back in the bottle once the disk ruptures. It is considered good practice to limit the pressure on the low side of the system to 10 psig to stay a safe distance away from disaster. Never exceed 10 psig whenever heating the chiller to raise the pressure.

Figure 28-44 Refrigerant escaping through a broken rupture disk on a low-pressure chiller.

Removing Compressor Oil

Compressor oil can contain a large amount of refrigerant. Heat the oil in the compressor to at least 130°F before removing it from the compressor. This will drive out most of the dissolved refrigerant while the oil is still in the system.

28.29 LARGE SCALE

Low-pressure chillers typically hold hundreds of pounds of refrigerant. A 30 lb portable recovery unit will not recover several hundred pounds of refrigerant. Low-pressure chillers usually have separate storage tanks and built-in recovery systems so that refrigerant can be pumped over into the auxiliary holding tank when the system needs to be opened (Figure 28-45). This is a slow process even with large on-site systems. Once the work is completed and the system is evacuated, the refrigerant is transferred back into the chiller. To aid

Figure 28-45 On-site recovery vessel for large low-pressure chiller. (Reftec International Systems, LLC)

in refrigerant transfer from the auxiliary storage tank back into the system, many of these storage tanks have built-in heaters that keep the refrigerant pressure up in the storage cylinder when the refrigerant is transferred from them back into the system.

Recovery equipment designed for use with Type III low-pressure systems should have a high-pressure cutoff at 10 psig to avoid over-pressurizing the system and blowing the rupture disk.

28.30 RECOVERING REFRIGERANT FROM SYSTEMS WITH LEAKS

Occasionally, a technician will check the pressure on a system that needs to have refrigerant recovered only to find that the system pressure is 0 psig. It is important to recognize that a pressure of 0 psig does not indicate that the system is completely empty. The correct procedure to follow is determined by the type of system and refrigerant. If it is a Type I system, no further action is necessary. The system may be opened without any further recovery efforts.

If a Type II system has a pressure of 0 psig, the remaining refrigerant must be recovered if the refrigerant type and amount require a vacuum below 0 psig. However, 0 psig may be considered an adequate recovery level for systems with leaks, because the EPA allows recovery to stop at the lowest practical level on systems with leaks. That level cannot be any higher than 0 psig.

The steps for recovering refrigerant from a system with known leaks are as follows:

1. Isolate the leaking part from the rest of the system. Now the rest of the system can be evacuated to the specified level without sucking in any air.
2. Evacuate the rest of the system to the specified level.
3. Recover the leaking part of the system to the lowest practical level. Of course, that must be no higher than 0 psig.

28.31 RECOVERED REFRIGERANT CONTAMINANTS

Recovered refrigerant may contain many contaminants, including refrigerant oil, acids, and water. After recovering the refrigerant, the technician must determine if it qualifies as hazardous waste. It may qualify as a hazardous waste if it is corrosive or contains heavy metals or is carcinogenic or extremely flammable. If it is determined that the recovered refrigerant is indeed hazardous waste, a whole new set of EPA rules for the handling and disposal of hazardous waste must be followed!

Recycled and reclaimed refrigerants are exempt from the hazardous waste rules, but recovered refrigerant is not. This is a very good reason to make certain that the refrigerant passes through a filter when it is recovered. Passing the refrigerant through a filter makes the refrigerant recycled and exempt from hazardous waste regulations.

Refrigerant Oil

Refrigerant oil is also recovered when recovering refrigerant. More oil comes out with liquid recovery than with

vapor recovery. This is not a problem if the system will be recharged with the recovered refrigerant, because most of the oil removed will go back into the system with the refrigerant. Oil that is the result of a recycling or reclaiming process is exempt from the hazardous substance rules, provided it is not mixed with other types of oil and is not burned.

Avoid Mixing Refrigerants

Avoid mixing refrigerants when recovering refrigerant. Mixed refrigerants can be very difficult to separate and frequently must be destroyed. Not only does this reduce the available supply of refrigerant, but it is expensive. Most refrigerant reclaimers will take relatively clean refrigerant for a reasonable fee but charge a high disposal fee for mixed or severely contaminated refrigerant. Each recovery cylinder should be used for only one type of refrigerant. Most recovery machines may be used for more than one type of refrigerant, but the refrigerant remaining in the recovery unit must be removed before the recovery unit is used on a different refrigerant. Follow the recovery unit manufacturer's instructions to change the system from one type of refrigerant to another. Typical steps for older systems include changing the oil in the recovery unit compressor, changing the filter, and evacuating the unit with a vacuum pump. Newer oil-less systems do not require an oil change.

28.32 DISPOSING OF RECOVERED REFRIGERANT

Recovered or recycled refrigerant may be reused if it does not change ownership. Refrigerant that has been recovered so that a mechanical repair can be performed is the best candidate for reuse. Refrigerant from compressor burn-outs, systems that have experienced multiple compressor failures, or systems that are contaminated with air or moisture are not good candidates for reusing refrigerant. The refrigerant is a minor cost in most systems. Replacing the refrigerant with new, clean refrigerant after performing repairs will increase the system's chances for a long and productive life. However, replacing the refrigerant requires that the technician dispose of the old refrigerant.

The recovered refrigerant is normally returned to a refrigerant reclaimer or manufacturer. This can be accomplished through a local wholesaler, or the refrigerant may often be sent directly to the processor. When refrigerant is shipped, the cylinders must be marked according to both DOT and EPA regulations.

DOT Labeling Requirements

For nonflammable refrigerants, the Code of Federal Regulations (CFR) 49 requires that each cylinder display a DOT diamond (square-on-point) "nonflammable gas" label (Figure 28-46). Each container of a regulated material should be marked with a DOT proper shipping name. This will be a generic chemical name, not a proprietary trade name. Each shipping container should list the consignor's name and address.

Figure 28-46 The DOT requires this marking on refrigerant cylinders while being shipped.

EPA Labeling Requirements

Each cylinder, ton tank, or drum containing a recovered refrigerant designated by the EPA as a Class I (CFC) or Class II (HCFC) substance in the Clean Air Act is required to display a warning statement indicating that the product(s) inside the cylinder or drum harms the earth's ozone layer. The chemical name of the substance may be abbreviated. For example, R-12 may be substituted for dichlorodifluoromethane.

The warning statement is as follows:

"WARNING: Contains [insert name of substance], which harms public health and environment by destroying ozone in the upper atmosphere" (Figure 28-47).

- Reclaimed refrigerant must meet AHRI 700 standard
- Certification of recycling and recovery equipment beginning November 15, 1993
- Refrigerant recovery levels established
- Repair of substantial leaks in equipment with a charge greater than 50 lb
- Safe disposal of appliances containing ozone-depleting refrigerant

Regulations outlining procedures for reducing ozone-depleting refrigerants divide refrigeration systems into three categories:

Type I	Small appliances that are hermetically sealed and contain 5 lb or less refrigerant
Type II	High-pressure appliances whose refrigerant has a boiling point between –58°F and 50°F and very-high-pressure appliances whose refrigerant has a boiling point below –58°F
Type III	Low-pressure appliances that use a refrigerant having a boiling point at atmospheric pressure above 58°F

The EPA certification exam consists of four parts: Core, Type I, Type II, and Type III. To become certified, technicians must pass the Core and at least one of the other sections. Refrigerant that has been removed from a system is classified as one of the following:

Recovered	Removed in any condition from an appliance and stored in external container without necessarily testing or processing it in any way
Recycled	Cleaned using oil separation and single or multiple passes through replaceable core filter driers
Reclaimed	Reprocessed to at least the purity specified in the AHRI Standard 700-1996, Specifications for Fluorocarbon Refrigerants

Recovered and recycled refrigerant may be charged into the system it came from or another system of the same owner. Reclaimed refrigerant may be used anywhere new refrigerant may be used. Refrigerant recovery can be accelerated through proper technique, including the following:

- If possible, operate the system before beginning refrigerant recovery.
- Use the large-diameter, short-length hoses.
- Recover liquid first.
- Begin recovery at the lowest available access point.
- Heat the system from which refrigerant is being recovered.
- Cool the cylinder the refrigerant is going into.
- Recover from both sides of the system during vapor recovery.

Nonrefillable refrigerant cylinders should not be used for refrigerant recovery. Recovery cylinders are gray with a yellow top and have DOT specifications stamped on them identifying the cylinder specifications. They should not be filled over 80 percent by volume.

UNIT 28—SUMMARY

The Montreal Protocol is an international treaty first passed in 1987 that established specific goals for the reduction of ozone depleting substances. Section 608 of Title VI of the 1990 Clean Air Act established regulations to reduce emissions of ozone-depleting substances from stationary refrigeration and air-conditioning equipment. Important aspects of this regulation include the following:

- A prohibition on venting ozone-depleting refrigerants
- Technician certification requirement starting November 14, 1994
- Restrictions on the sale of ozone-depleting refrigerants starting November 14, 1994

Refrigeration systems should be leak tested before charging or whenever refrigerant needs to be added. Leak testing techniques include the following:

- Soap bubble solutions
- Halide torches, which work only on chlorinated refrigerants
- Ultrasonic leak detectors, which detect the sound of refrigerant escaping
- Electronic sniffers, which detect CFC, HCFC, and HFC refrigerants
- Dyes that make oil spots more visible
- Standing vacuum test
- Standing pressure test

Significant leaks in systems that hold 50 lb of refrigerant or more must be repaired. A significant leak is defined as an annual leak rate of 35 percent of the charge for commercial and industrial refrigeration or an annual leak rate of 15 percent of the charge for air-conditioning systems and other applications.

WORK ORDERS

Service Ticket 2801

Work to Be Performed: Liquid-Line Filter Replacement

Equipment Type: R22 Split-System Air Conditioner with 30 lb of Refrigerant

Since this is an R-22 system that holds less than 200 lb of refrigerant, the recovery level is 0 psig. The technician decides to pump the system down using the liquid-line service valve to save time. The liquid-line service valve is front-seated and the system is operated. The system is shut down when the liquid-line pressure reaches 0 psig. The technician waits to make sure the pressure will hold. It does. The old filter is removed and the new filter installed. Nitrogen is added to the liquid line to check the connections for leaks. After performing the leak test, the nitrogen is released to the air. A vacuum pump is used to evacuate the liquid line and low side. Then the liquid-line service valve is back-seated and the system returned to operation.

Service Ticket 2802

Work to Be Performed: Compressor Change-out

Equipment Type: R-410A Split-System Air Conditioner with 7 lb of Refrigerant

A technician needs to change a compressor with a bad burnout. The technician selects a recovery system that is rated for R-410A refrigerant. The recovery cylinder is a 4BA-400 to handle the higher pressures. The gauges are connected to the liquid and suction service valves. The center hose connects to an inline filter. Another hose connects to the recovery unit, and a hose with a positive shutoff adapter is connected from the recovery unit to the recovery cylinder. The technician begins liquid recovery

from the high side only. Once no more liquid is being removed, the recovery valves are set to vapor recovery, and both manifold gauge valves are open to allow vapor recovery from both sides of the system. The recovery unit runs until the system pressure is 5 in Hg vacuum, slightly lower than the required recovery level of 0 psig. The gauges are closed and the recovery units shut off. The system pressure rises slightly after sitting but remains below 0 psig. The technician replaces the compressor, installs both liquid and suction-line filter driers, and pulls a deep vacuum on the system. The system is recharged with new R-410A. The recovered R-410A is returned to the refrigerant wholesaler, who sends it off for reclaiming.

Service Ticket 2803

Work to Be Performed: Refrigerant Added

Equipment Type: R-22 Split-System Air Conditioner with 50 lb of Refrigerant

A customer asks the local air-conditioning contractor to add charge to his commercial air-conditioning unit, stating that he always needs to add some every spring. The technician checks the system charge and finds that it is indeed low. The system requires 10 lb of charge. The technician informs the customer that the system has a leak that exceeds the allowable rate of 15 percent of the charge per year. The owner says that he really does not want to spend money repairing the system, and the technician informs the owner that the system must be repaired or mothballed, or a plan must be developed to replace the system. (Mothballing requires recovering the system's refrigerant and taking it permanently out of service.) The owner decides to replace the system but wants to operate it for a while before replacing it. The technician tells him that he needs to submit a written plan to the regional EPA office outlining the plan to replace the equipment in no later than a year.

Service Ticket 2804

Work to Be Performed: Dispose of Refrigerator with a Dead Compressor

Equipment Type: Domestic Refrigerator with 12 oz of R-12 Refrigerant

A technician working for a scrap metal dealer is asked to prepare a domestic refrigerator for recycling. The compressor does not operate. The technician intends to use a system-dependent recovery device, so two sets of piercing pliers are used, one on each side of the compressor. The hose from each pair of piercing pliers is run to a tee that is connected to the inlet of the nonpressurized container (bag). The bag begins to increase in volume as the refrigerant travels from the refrigerator to the bag. The compressor is heated with a hair drier and struck three times with a hammer. The pliers and hoses are removed and the bag capped.

23. When did it become illegal to vent replacement refrigerants?
24. How can a technician identify what refrigerants a particular recovery machine is designed for?
25. Determine the weight of a recovery cylinder when safely filled with the following specifications: tare weight of 20 lb; water capacity of 30 lb; refrigerant specific gravity of 1.1.

UNIT 29

Refrigerant Leak Testing

OBJECTIVES

After completing this unit, you will be able to:

1. list issues to check for in a preliminary visual leak-prevention inspection.
2. explain the trigger rates that require mandatory leak repair.
3. discuss inert gas leak-detection techniques.
4. list types of refrigerant leak detection.
5. discuss proper refrigerant leak-detection techniques.
6. calculate the effect of ambient temperature change on a standing pressure test.
7. discuss leak-testing procedures for low-pressure systems.

29.1 INTRODUCTION

Reducing refrigerant emissions through good service practices, leak detection, and refrigerant recovery is a big part of any HVACR technician's job. Keeping refrigerant inside the system protects the environment, and leaking refrigeration systems are expensive. Not only does replacing the system refrigerant become costly, but the cost of operation also increases because of refrigerant leaks. A system operating undercharged because of a leak uses more energy to produce less cooling, leading to increased operating costs. Customers operating leaky systems may believe they are saving money by not paying for expensive repairs and just topping off the charge. Instead, they are paying for the repairs in the form of increased power bills, but they are not receiving the repairs or comfort they are paying for.

29.2 PREVENTING PROBLEMS

Systems should always be tested for leaks before they are charged. This saves time by eliminating the need to deal with leaking refrigerant, recovering refrigerant from the system to perform repairs, and evacuating the system multiple times. It is good service practice to take steps toward recognizing and fixing potential problems. When inspecting a system for leaks, take the time to do a quick preliminary visual inspection. Make sure refrigerant lines and joints have been assembled properly and are sufficiently braced and supported. Unsupported lines can put extra pressure on joints, leading to eventual failure. Unbraced lines can transmit vibrations that can cause leaks. Look for any metal-to-metal contact points on the refrigerant lines. Any contact with a hard surface can cause leaks at the contact point. Refrigerant lines should not come into direct contact with concrete, as chemicals in the concrete can cause corrosion, leading to leaks.

29.3 SIGNS OF REFRIGERANT LEAKAGE

There are several signs of refrigerant leakage that technicians should be aware of. Refrigerant oil travels with the refrigerant in the system. Trace amounts of oil will escape

with the refrigerant leaking out. Over a period of time, the area around the leak will appear oily. Often the oil will attract dust and dirt, making an oily dirt buildup around the leak area. Systems operating with leaks will have a high system superheat and a low system subcooling and low capacity because of the lack of refrigerant. Unit 31, Refrigerant System Charging, discusses how a system charge affects both the superheat and subcooling. The compressor will be hotter than normal because the reduced amount of refrigerant circulating through the system does not cool the compressor as well.

29.4 TRIGGER RATES

Leak testing is an important part of reducing refrigerant emissions. Systems should be leak tested before charging or recharging them with refrigerant. Good service practice demands finding and repairing leaks on all systems. The EPA only requires repairing leaks on systems with a refrigerant charge of 50 lb or more that have leaks meeting EPA established trigger rates. The trigger rate for commercial and industrial process refrigeration is an annual leak rate of 35 percent of the total charge. Comfort cooling and "other" applications are restricted to an annual leak rate of 15 percent of the total charge. Note that the word *rate* includes the speed with which the refrigerant is lost. If a system that holds 100 lb of refrigerant loses 3 lb in a month, the leak rate is 36 lb per year. This leak would require repair, even if only 3 lb had escaped. The system owner is not allowed to wait until 35 percent of the charge has actually been lost before repairing the leak. The EPA uses owner maintenance records to prove that a system does not leak.

When technicians find a significant leak, they are required to inform owners in writing. The owner then has thirty days to repair the leak or submit a plan to the EPA to replace the system. The old unit can remain in service for up to a year if the plan is approved. Another way to put off either repairing or replacing the system is to mothball it. The leaky system does not have to be repaired or replaced if it is mothballed. The system may remain in this state indefinitely.

29.5 SYSTEM PRESSURE

Most leak-detection systems rely on detecting gas escaping from the leak. This assumes that there is still something in the system to escape. It does not matter what technique is used if there is no gas in the system to leak out. The first step should be to check the pressure on the system.

System Design Pressures

Most refrigeration systems have design pressures stamped on them (Figure 29-1). These are not the operating pressures but the pressures used for pressure testing the high and low sides at the factory. The system’s design pressures should never be exceeded when field testing a system! Think of the design pressure as the maximum pressure that can be applied to the system components during leak testing. The safest procedure is to never exceed the low-side design pressure, because it is difficult to ensure that the high side and low side of an installed system will remain segregated. If the system does not list a design pressure, use 150 psig as the maximum safe test pressure. Hermetic compressor manufacturers list 150 psig as the maximum safe test pressure on the compressor shell.

29.6 LEAK TESTING WITH INERT GAS

If a system is empty, it can be charged with refrigerant or with an inert gas. Inert gases do not cause any chemical reactions with the materials in the system, and they do not support combustion. Carbon dioxide and nitrogen are the two most common inert gases. It does not make sense to use refrigerant when locating a potentially large leak. Refrigerant is expensive and must be recovered, while inert gases are cheap and do not have to be recovered. They may simply be released to the air. There are two methods of detecting nitrogen leaking from a system: one involves soap bubbles and the other ultrasonic detectors.

Figure 29-2 Large leaks blow bubbles when a soapy solution is used.

SAFETY TIP

Any chemicals used on food service equipment, including soap bubbles, should be approved by NSF International. Using non-approved chemicals can result in sickness or injury to people who consume food prepared in that area.

Soap Bubbles

Soap bubbles and nitrogen can locate any major leaks in field fabrication. Escaping gas blows bubbles when a soapy solution is applied to the leaking area. Larger leaks will blow visible bubbles (Figure 29-2), while tiny leaks will form a white froth of micro-bubbles (Figure 29-3). Wait a few minutes after applying soap bubbles; micro-bubbles take a few minutes to show up. The EPA recommends using soap bubbles as the best method for pinpointing the location of leaks. Concentrate on mechanical joints first and then field-brazed joints.

Figure 29-3 Small leaks create micro-bubbles that collect into a froth after several minutes.

Figure 29-4 This leak detector produces micro-bubbles that froth to show small leaks.

SERVICE TIP

Chemical manufacturers that specialize in HVACR applications make soap bubbles specifically for the HVACR industry. While it is certainly possible to make your own using dishwashing detergent, they will not perform as well. This is particularly true when it comes to micro-bubbles. The leak detector shown in Figure 29-4 is specifically designed to produce micro-bubbles.

Ultrasonic

Ultrasonic leak detectors check for leaks by listening for the high-pitched whistle the gas makes as it escapes through small holes (Figure 29-5). The primary advantage of an ultrasonic detector is that it works for locating very small leaks with any gas, including nitrogen. Ultrasonic detectors usually have a way to “tune out” background noise and concentrate on the frequencies most likely to be caused by gas whistling through a small hole.

29.7 SAFETY WITH CO₂ AND NITROGEN

Nitrogen and CO₂ are inherently safe. They do not burn, they do not chemically react with many substances, and they are not poisonous. However, both can be dangerous because they do not irritate your lungs or eyes. There is little warning that the closed area a technician is in is so full of nitrogen that there is no longer enough oxygen to breathe; the technician will simply get dizzy and pass out.

Nitrogen and CO₂ cylinders can also be dangerous because of the very high pressures inside them. They typi-

cally have over 2,000 psig of pressure when the cylinder is new. A pressure regulator and pressure-relief valve should always be used when pressure testing with nitrogen or CO₂ (Figure 29-6). The regulator makes it possible to safely control the pressure on the system. The relief valve provides protection against accidental system overpressurization in the event of a regulator failure. There should be no other devices or valves connected to the outlet of the pressure-relief valve. Having something in the way of the outlet could prevent the valve from operating correctly.

Never Use Oxygen for Pressure Testing!

Never use oxygen or compressed air to pressurize a refrigeration system. Pure oxygen should be considered a dangerous gas because of the increased risk of fire. Mixtures of refrigeration oil and concentrated oxygen can be explosive. Compressed air contains substances that should not be inside a refrigeration system, including oxygen and water.

Figure 29-6 A pressure regulator and a pressure-relief valve should always be used when using nitrogen for pressure testing.

Figure 29-7 The red-hot copper disk breaks down the refrigerant when it passes over the disk.

29.8 USING R-22 AS A TRACE GAS

Mixtures of nitrogen and up to 10 percent R-22 may be used to check for leaks, using the R-22 as a trace gas. This allows the use of sensitive electronic sniffers that can detect the R-22. Mixing the R-22 with the nitrogen reduces the amount of refrigerant being released. Mixtures of R-22 and nitrogen may be released without being recovered, but nitrogen may not be put in on top of existing R-22. The system must be evacuated first, and then the R-22 and nitrogen mixture is added. From an environmental standpoint, testing with 100 percent nitrogen is preferable to testing with R-22 and nitrogen mixtures.

29.9 LEAK TESTING WITH HALIDE TORCHES

Halide torches were once one of the most popular forms of leak-detection devices for chlorinated refrigerants. However, halide torches are disappearing as chlorinated refrigerants are phased out. The flame of a halide torch keeps a copper disk red hot (Figure 29-7). Combustion air is drawn through a small hose, passing over the copper disk. The red-hot disk decomposes any chlorinated refrigerant passing over it, and the flame color changes. Mixtures of CFC or HCFC refrigerant and air turn the flame green (Figure 29-8).

Figure 29-8 Most leaks cause a pale green flame color.

The brightness and intensity of the green color is directly related to the concentration of refrigerant. Higher refrigerant concentrations are indicated by a greener flame. Halide torches work well with CFC and HCFC refrigerants, but they do not work with HFC refrigerants because HFCs contain no chlorine. Of course, a halide torch should never be used to check for leaks of flammable refrigerant. Also be aware that the fumes produced by a halide torch can be very irritating because halogenated refrigerants break down when passed through a flame. This is normally not a very great hazard because the amount of refrigerant passing through the flame is small.

29.10 LEAK TESTING WITH ELECTRONIC SNIFFERS

Electronic leak detectors have largely replaced halide torches (Figure 29-9). They have been around for a long time, but electronic detectors have become the standard in leak detection since the era of the Clean Air Act and refrigerant conservation. Electronic leak detectors are advertised to be able to detect leaks as small as 0.25 oz per year. In practice, hypersensitivity can actually be a detriment to locating the exact location of a leak. This is why the EPA considers electronic sniffers the best tools for locating the

Figure 29-9 Electronic leak detectors.

general area of a leak but soap bubbles as the best tool for pinpointing the leak source.

Important questions to ask when choosing an electronic sniffer would be as follows:

- What types of refrigerants will the detector detect?
- How long will the tip or sensor last before it needs replacing?
- How much does the tip or sensor cost to replace?
- How quickly does the instrument clear itself after finding a leak?
- What types of things can cause false alarms with the instrument?

29.11 CORONA DISCHARGE LEAK DETECTORS

The first electronic leak detectors used corona discharge technology (Figure 29-10). The corona is a high-voltage discharge that ionizes the gas it passes through. Anything

Figure 29-10 Older-style corona discharge electronic detector.

Figure 29-11 Heated diode electronic leak detector.

that breaks that corona barrier can set off the detector, including dust, moisture, refrigerant, or a good gust of wind. Corona discharge tips tend to become unreliable after as little as 20 hours of use. Fortunately, the tips are normally not expensive, and this type of detector can usually be restored to reliable operation by changing the tip. Most corona discharge units continue to squeal for a long time after they are removed from the leak source, which makes locating exactly where the leak is more difficult. They also give false readings when wind blows on them or when the tip is tapped against something.

29.12 HEATED DIODE LEAK DETECTORS

Heated diodes are a newer technology that has proven to be sturdier and more reliable (Figure 29-11). Their tips last much longer than the corona discharge units, but they are more expensive to replace. Heated diode detectors use heated electrochemical sensors. When a CFC, HFC, or HCFC contacts with the hot surface, the chlorine and fluorine atoms are separated from the molecule and ionized. This causes an electrical current flow in the sensor, indicating the leak. Heated diode instruments tend to clear themselves quickly. This aids in tracking down the actual location of the leak and differentiating leaks from ambient contamination. Heated diode detectors are not set off by wind.

29.13 INFRARED LEAK DETECTORS

The newest handheld electronic leak detectors use infrared sensors (Figure 29-12). They are not affected by wind, water, or oil, and the sensor life is measured in years instead of hours. Refrigerant reflects infrared light. Refrigerant is drawn into the tip and travels between an infrared light source and an infrared light sensor. When refrigerant enters

Figure 29-12 This handheld electronic leak detector uses an infrared sensor.

the tip, it reflects the infrared radiation and blocks the sensor from seeing it, much like a cloud can block the sun on a cloudy day. The detector senses the change and indicates a leak. IR sensors detect change. If the level of refrigerant stays the same, the detector stops alarming. Because of this, they are used differently from heated diode detectors. You sweep the detector back and forth, narrowing your target area.

29.14 LEAK TESTING WITH DYES

Refrigerant dyes have been around for many years. The idea is for the escaping refrigerant to leave a visible trail. These dyes do not really dye the refrigerant but the refrigerant oil. Since refrigerant oil travels throughout the system with the refrigerant, oil normally leaks out with the refrigerant. A well-known trick of the trade is to look for oily spots on or around systems when trying to find difficult leaks (Figure 29-13). The dye simply makes this more visible.

SERVICE TIP

It is important to make sure the dye you use is compatible with the oil in the system. Some dyes are designed for specific kinds of refrigerant oil. Check the label on the dye to make sure it is compatible with your system. Figure 29-14 shows the application notes on a container of dye.

Figure 29-13 Oily spots around mechanical or brazed joints can indicate a refrigerant leak.

Two types of dye are available: red and fluorescent. The red dye turns the oil in the compressor a very dark red. Red dye does just what you would expect: it shows leaks by creating a red stain anywhere refrigerant escapes. Fluorescent dye shows up when exposed to ultraviolet light (Figure 29-15). Ultraviolet dye is useful for locating leaks in unusual locations. These “hidden” leaks are often in areas that you would normally not suspect, such as a pinhole in the side of a receiver. Dyes can be an excellent tool for people doing regular maintenance on the same machines. Systems with dye previously installed can be quickly checked using a high-wattage black light.

The dye is available as an additive or loaded in refrigerant cylinders (Figure 29-16). Refrigerant that is already mixed with dye must leave the cylinder as a liquid to keep the dye in solution. The refrigerant charge in the cylinder forces the dye into the system. Dye is most often sold in small cylinders of dye called dye sticks. These have 1/4-in flare ports on both ends to allow connection of standard refrigeration fittings. Valves are connected to both ends to allow control of refrigerant through the dye stick. Make

Figure 29-14 The instructions on this dye stick package indicate the type of refrigerant oil it is compatible with.

Figure 29-16 Red dye additive.

certain the bleed valves are closed, and then connect short refrigeration hoses between the low-side and high-side service valves and the dye stick. The arrow on the dye stick should point toward the low-side service valve (Figure 29-17). Purge the air out of each hose by loosening the hose connection at the bleed valves. Crack the bleed valve on the inlet side of the dye stick and then crack the bleed valve on the outlet side. The system pressure will force the dye into the low side of the system.

Figure 29-17 The dye stick is connected between the high side and low side with the arrow pointing toward the low side.

CAUTION

Do not open the bleed valves all the way. Pushing the dye into the system too quickly can cause a liquid slug and kill the compressor.

Dye is not a one-call method. The dye and oil must have time to circulate in the system before the leaks will show up. A major problem with dyes is that they are messy. Expect a mess every time gauges are connected and disconnected (Figure 29-18). It is necessary to clean up the mess, because it might otherwise lead someone to suspect a leak where the dye has sprayed. Cleaning solutions made specifically for cleaning the dye should be used to clean up before leaving (Figure 29-19). Many equipment manufacturers do not endorse the use of dyes, so check with the equipment manufacturer before adding dye to a system. The use of dyes in some manufacturers' equipment will void the warranty.

29.15 ULTRAVIOLET LEAK-DETECTION LIGHTS

Ultraviolet bulbs that produce UV light with a wavelength of 375 nm are required to find leaks indicated by the fluorescent dye. Older UV lights were large, required 120 volts, and

Figure 29-18 The spray pattern makes a mess when refrigerant gauges are removed from a system containing dye; the top picture shows what the area looks like without the black light; the bottom picture shows the same area with the black light; this should be cleaned up before leaving the job.

used expensive mercury vapor bulbs. Figure 29-20 shows an example of an early model UV light. Newer models use battery-powered LED lights. These are far easier to use and less costly to maintain. Figure 29-21 shows a newer flashlight-style LED UV light for leak detection.

Figure 29-19 This cleaning solution is made specifically for cleaning up dye.

Figure 29-20 Older UV light used to detect fluorescent dyes.

Figure 29-21 Newer LED flashlight-style UV light used to detect fluorescent dyes.

TECH TIP

It is important to get the right UV light. All UV light is not the same wavelength. UV just means the light waves are shorter than normal visible light. Inexpensive lights used for black-light posters will usually not work well because they don't have the right wavelength of light to show the indicator dye.

29.16 PROVING THE SYSTEM IS TIGHT

There are two methods of proving a system is free of leaks that do not involve checking for escaping gas:

- Standing pressure test
- Standing vacuum test

Standing Pressure Test

A standing pressure test involves charging an empty system with an inert gas, recording the pressure, and then checking back later to see if the pressure has dropped. This method is only valid when the system is charged with a gas that cannot possibly condense at the pressure and temperature found in the system because a saturated mixture of liquid and gas refrigerant would change pressure significantly as the ambient temperature changes. A drop in pressure might just reflect a drop in temperature and not a leak. Also, the refrigerant pressure will remain the same at a saturated condition as long as the system temperature remains stable. As long as there is still some liquid in the system, the pressure in the system will be controlled by the temperature, not by the amount of refrigerant in the system. Therefore, a system could have a leak, lose refrigerant, and not see a drop in pressure.

Temperature change will affect the system pressure even if all the gas is in vapor form, but the change will not be as pronounced. The absolute pressure of a gas varies directly with its absolute temperature. The gas laws can be used to predict the effect of temperature. If a system with a pressure of 85 psig and a temperature of 100°F changes to a temperature of 50°F, the pressure would be reduced to 76 psig.

Converting those temperatures to absolute temperature yields a temperature change of 560°R to 510°R. That ratio is 510/560, or approximately 0.91. Multiplying this ratio times an absolute pressure of 100 psia gives 91 psia. 91 psia is 76 psig converted to gauge pressure.

Standing Vacuum Test

It is common practice to wait after pulling a deep vacuum on a system to ensure that the pressure will not rise. A rise in pressure can be interpreted as air entering the system through a leak. Of course, other factors can also cause a rise in system pressure after an evacuation, such as system contamination, slow evaporation of refrigerant dissolved in the compressor oil, or simply reading the vacuum near the vacuum pump instead of near the system.

29.17 LOW-PRESSURE SYSTEMS

Leak testing low-pressure chillers is entirely different from leak testing high-pressure systems. Because the evaporator on a low-pressure system operates in a vacuum, refrigerant does not leak out of a low-side leak. Air leaks in instead. One sign of leaks in a low-pressure system is extended purge operation. When a chiller is leaking, the air sucked in through the leaks forces the purge system to operate more to remove the air. Technicians need to raise the evaporator pressure above 0 psig to detect a refrigerant leak. This can be done by either raising the temperature of the water in the chiller bundle or by adding nitrogen. The preferred method for raising the system pressure is to circulate warm water through the chiller bundle. The advantage of this method is that you are not introducing a noncondensable gas that will have to be removed through purge operation. Either way, it is important to keep the pressure under 10 psig. Chillers have rupture disks that open at 15 psig, releasing the refrigerant in the chiller. This is to prevent the chiller from being pressurized beyond its design limits.

UNIT 29—SUMMARY

Refrigeration systems should be leak tested before charging or whenever refrigerant needs to be added. Leak testing techniques include the following:

- Soap bubble solutions
- Halide torches, which work only on chlorinated refrigerants
- Ultrasonic leak detectors, which detect the sound of refrigerant escaping
- Electronic sniffers, which detect CFC, HCFC, and HFC refrigerants
- Dyes that make oil spots more visible
- Standing vacuum test

Significant leaks in systems that hold 50 lb of refrigerant or more must be repaired. A significant leak is defined as an annual leak rate of 35 percent of the charge for commercial and industrial refrigeration or an annual leak rate of 15 percent of the charge for air-conditioning systems and other applications.

WORK ORDERS

Service Ticket 2901

Work to Be Performed: Run Refrigerant Lines

Equipment Type: R-404A Commercial Refrigeration System

A system installer is asked to run refrigerant lines for a new commercial refrigeration installation. After running the lines, the installer pressurizes the lines with 100

psig of nitrogen to check for leaks. The installer uses soap bubbles at the joints to check for leaks. One joint indicates a leak by forming large bubbles. The nitrogen is released, and the braze joint is redone. The lines are pressurized once more with nitrogen and checked with soap bubbles again. No large bubbles appear on the repaired joint, but a small clump of frothy bubbles appears on another joint. The nitrogen is released, that joint is redone, and the system is checked again. No bubbles or froth appears this time. Because of the multiple leak problems, the installer decides to perform a standing pressure test. The equalized system pressure and temperature are recorded. The next day the installer calculates the expected pressure change due to temperature change and finds the system pressure matches the calculations. The installer releases the nitrogen, pulls a deep vacuum on the system, and charges it to factory specifications.

Work to Be Performed: Find Elusive Refrigerant Leak

Equipment Type: R-22 Split-System Heat Pump

A split-system heat pump has lost a small amount of refrigerant each year, and it seems to be getting worse. The technician installs gauges to make sure the system has pressure, which it does. Leaving the system off, the technician uses a heated diode electronic leak detector to check inside the evaporator and condenser cabinets for puddled refrigerant vapor near the bottom of the cabinet. The leak detector goes off in the evaporator cabinet. The technician is unable to locate the specific leak location. Fluorescent dye is added to the system and the system charge is brought back up to normal. The system is operated for a week. The technician returns and inspects the evaporator area with an ultraviolet light. Small, bright streaks appear in several locations on the coil where the tubing passes through the endplate. The technician informs the customer that he needs a new evaporator coil.

UNIT 30

Refrigerant System Evacuation

OBJECTIVES

After completing this unit, you will be able to:

1. list the reasons for evacuating a refrigeration system.
2. describe the effects noncondensable gas has on refrigeration systems.
3. describe the effect moisture has on refrigeration systems.
4. explain how to measure a deep vacuum.
5. explain the system of measuring vacuum in microns.
6. describe the ways that the vacuum pump and vacuum gauges can be connected to the system.

30.1 INTRODUCTION

The operating efficiency and life of the compressor both depend heavily on the proper evacuation and charging of the refrigerant circuit. Evacuation to the proper levels is critical to ensure the system has been dehydrated and all noncondensables have been removed. Leaving noncondensable gases in the system increases the system head pressure and compression ratio. These adverse system reactions to noncondensable gases decrease system capacity and efficiency while increasing energy use. Any moisture or noncondensable gas left in the system significantly affects the system's performance and can have a devastating effect on the compressor's longevity. Water can freeze up in the metering device, starving the evaporator and decreasing system capacity. Water can also hydrolyze refrigerant oil to form acid, leading to internal system corrosion.

30.2 LEAK TESTING

Refrigeration systems should always be checked for leaks prior to evacuation. Attempting to evacuate a leaky system will only suck air into it through the leak. Checking for leaks prior to evacuating saves time in the long run, because time spent evacuating a leaky system is wasted. Refer to Unit 29, Refrigerant Leak Testing, for more information on how to test refrigeration systems for leaks.

30.3 THE PURPOSE OF EVACUATION

The only two things that should be circulating inside a refrigeration system are refrigerant and refrigerant oil. Additional gases and/or liquids degrade system performance and reduce equipment life. The purpose of pulling a deep vacuum on a system is to have nothing but refrigeration oil in the system before charging it with refrigerant. Proper evacuation of a unit will remove noncondensables and water. Other contaminants, such as brazing oxides and metal particles, must be removed using a filter drier. When properly done, evacuation also ensures a leak-tight system, because systems with leaks will not pull down into a deep vacuum and hold.

TECH TIP

Evacuation cannot completely dehydrate systems that use hygroscopic lubricants, such as polyol ester (POE) or polyalkylene glycol (PAG) lubricants. Moisture can only be removed from these lubricants using a filter drier. That is why newer HFC systems with POE lubricant require a filter drier in new installations in addition to a thorough evacuation. Note that the filter drier does not eliminate the need for evacuation. The filter can only remove small quantities of moisture and cannot remove noncondensable gas at all.

30.4 SYSTEM CONTAMINANTS

Since a vacuum pump only removes gas, an evacuation can only remove substances that can be in vapor form at normal ambient temperatures under a deep vacuum. Solid contaminants like copper chips or carbon must be filtered out. However, the two most common system contaminants can be removed through evacuation. They are noncondensable gases and moisture.

Noncondensable Gases

Noncondensables are gases that cannot condense at the normal system pressures and temperatures, such as air or nitrogen. The primary problem caused by noncondensable gases is an increase in the system high-side pressure and temperature (Figure 30-1). The pressure of the noncondensable gases is added to the refrigerant pressure, according to Dalton's law. Noncondensable gases tend to collect in the condenser since they do not condense. This has the effect of reducing the amount of condenser surface available for condensing refrigerant, increasing the refrigerant temperature and pressure. The effect of the additional pressure is to increase the compression ratio and decrease the amount of refrigerant circulated. This reduces system capacity, increase energy usage, and leads to compressor overheating.

Figure 30-1 Noncondensables in the condenser raise the system high-side pressure.

Air in the system can cause chemical damage as well. Oxygen is one of nature's most chemically active elements. Its rate of chemical reaction with refrigeration oil increases very rapidly with a rise in temperature above 200°F. The rate of chemical reaction between oil and oxygen doubles with every 18°F rise in temperature above 200°F. When this occurs, the oil starts to break down and deposits buildup in the discharge valve area. Further, this breakdown of refrigerant creates an acid condition that leads to compressor motor burnouts. A chain of events with ever-increasing system malignancy develops that leads to system failure.

TECH TIP

The number of systems with large amounts of noncondensables appears to be increasing. Installers that are in too much of a hurry to evacuate systems are leaving large quantities of air in systems. Simply opening the system charging valves after connecting the refrigerant lines traps the air from the lines and indoor coil inside the system. These systems operate with a very high head pressure, a hot compressor, and poor cooling efficiency. The only fix for this once it has been done is to recover all the refrigerant and air in the system into a separate empty recovery cylinder, properly evacuate the entire system, and weigh in the correct charge.

Water

Water is another formidable foe of the refrigeration system. A single drop of water can cause a major blockage of the refrigerant flow within a system by freezing up at the metering device. Water can also cause a breakdown of the refrigerant oils and the refrigerant used in a system. This makes moisture the greatest of all enemies to the inside of the refrigeration system, especially units equipped with hermetic compressors.

The primary ill effects of moisture in the system are:

- Freeze-up at the expansion valve or metering device
- Corrosion of metals
- Valve failure
- Copper plating
- Chemical damage to motor insulation

System Freeze-up

A freeze-up at the metering device occurs when small droplets of water freeze and form ice crystals. This occurs whenever the system temperature drops below the water's freezing point. The flashing of refrigerant at the metering device can cool the water enough to freeze it, creating a restriction.

System Corrosion

Most metals corrode on contact with moisture and oxygen. This can occur inside the refrigeration system when both moisture and air are present; corrosion starts eating away at the metal. This reaction increases with heat. The presence of noncondensables increases the compressor temperature and accelerates the chemical activity of the water and oxygen. Corrosion is not a problem in a properly evacuated and charged system.

Acid Creation

Moisture, when teamed with refrigerant in the refrigeration system, will create acid. Acid in the system can cause a burnout when the refrigerant is exposed to the compressor motor. The acidic reaction increases when heat is added to moisture and refrigerant. An ever-increasing upward spiral of acid level is created, and temperature increases eventually leads to compressor motor burnout.

30.5 MEASURING VACUUM LEVEL

A vacuum is any pressure less than atmospheric pressure. Vacuums can be measured by specifying how much of the atmospheric pressure has been removed or by specifying how much pressure remains. Atmospheric pressure is typically measured by how high a mercury column it will support. Standard atmospheric pressure at sea level is 29.92 inches of mercury, abbreviated in Hg (Figure 30-2). Mercury columns can be used to measure vacuum by measuring how much pressure has been removed. A 20 in Hg vacuum means that the pressure is 20 inches of mercury less than atmospheric pressure (Figure 30-3). Since atmospheric pressure is 29.92 in Hg, a perfect vacuum would be 29.92 in Hg vacuum. This would indicate that all the pressure had been removed.

Figure 30-2 Atmospheric pressure will support a mercury column 29.92 in high.

Figure 30-3 The pressure in a 20-in mercury vacuum is 20 in less than atmospheric pressure; this leaves 9.92 in of mercury remaining.

Absolute Pressure

Absolute pressure can be used to measure vacuum by measuring how much pressure is left. In the case of a 20 in Hg vacuum, the absolute pressure would be 9.92 in Hg absolute because 9.92 inches of the original 29.92 inches of pressure are left (see Figure 30-3). A perfect vacuum using absolute measurement would be 0 inches of mercury absolute. This indicates that no pressure remains.

The problem with both of these methods is that an inch is far too large and imprecise a measurement to tell the difference between a really good vacuum and a poor one. Most equipment manufacturers now specify the required vacuum level in microns of mercury absolute pressure, normally shortened to just microns for simplicity.

Microns

A micron is a very small measurement of distance equal to 1/1,000 of a millimeter. There are approximately 25,400 microns in an inch. When vacuum is measured in microns, what is actually being measured is how much pressure remains in the system, not how much pressure has been removed. Absolute pressure is what is really being specified. Enough pressure remains in a 500-micron vacuum to support a column of mercury 500 microns high, or 1/2 mm. To put this number in perspective, full atmospheric pressure can support a mercury column 760,000 microns high. Of the initial 760,000 microns, only 500 are left.

30.6 SYSTEM EVACUATION

Evacuation is the process of removing gases from the refrigeration system. Gases removed from refrigeration systems by a vacuum pump include air, nitrogen, residual refrigerant, and water vapor. The majority of the gases in a refrigeration system can be evacuated in a few minutes. It normally does not take long to remove air and noncondensables, since they are already a gas. Achieving a deep vacuum on

a system that is dry takes much less time than on a system that is contaminated with moisture. However, removing air and noncondensables is only one reason for evacuating a refrigeration system. Evacuating a system is also one of the principle means of dehydrating it.

SERVICE TIP

Listening to the sound of a vacuum pump can tell you something about what it is pulling out of the system. Most deep vacuum pumps operate under oil. The gas being evacuated gurgles as it goes through the pump. When the gurgling noise stops, the pump has removed most of the noncondensable gas from the system. This is the point where the pump starts to dehydrate the system. If the gurgling noise never goes away, either the system or the connections are leaking and letting in a constant stream of air.

30.7 SYSTEM DEHYDRATION

Dehydration is the process of removing moisture from a refrigeration system. Moisture in a system may exist as liquid or vapor. Water vapor is removed quickly along with the noncondensables. However, the water in liquid form must be vaporized before it can be removed. The amount of gas created when even a small amount of water is vaporized is quite large. Vaporizing an ounce of water at an absolute pressure of 1,000 microns of mercury creates over 500 ft³ of water vapor (Figure 30-4). It would take a 5-CFM (cubic feet per meter) vacuum pump an hour and 40 minutes to remove this much vapor! For this reason, the best practice when doing refrigeration work is to avoid letting any water into the system in the first place. That is why all refrigeration components and refrigeration lines should be sealed when not in use.

Water in Compressor Oil

The time estimate in the above example assumes that the water is able to vaporize easily. However, water that collects below the refrigerant oil in the compressor crankcase can be more difficult to remove. Striking the compressor and applying heat to the compressor crankcase can help

remove water from underneath mineral oil. A filter drier is the only reliable way to remove water from hygroscopic refrigerant oil such as polyol ester. Even a deep evacuation will normally not remove water that has been absorbed into polyol ester lubricant.

Sublimation

It is possible to have ice inside the system when systems are assembled in below-freezing conditions. Frozen water can be evaporated through sublimation. Sublimation is the process of turning a solid into a gas without passing through the liquid stage. The vapor that comes off of dry ice is an example of sublimation (Figure 30-5). It is possible to dehydrate a system with ice inside it, but it is a very slow process. Heating any part of the system that is below freezing will speed up evacuation and dehydration if it has any moisture in it.

Speeding up Dehydration

During evacuation, the vacuum level in a system that has moisture in it will appear to get stuck between 1,500–5,000 microns. This is because the vaporizing water continually replaces the gas that is removed by the vacuum pump, preventing the pressure from dropping. If a system is suspected of having liquid water anywhere in it, every effort should be made to remove the water from the system prior to evacuation. Following good refrigeration practices will prevent water from getting into the system in the first place. Heating any part of the system that is suspected of having moisture in it will speed up evacuation and dehydration by helping the water vaporize quickly. Systems should be evacuated from both the high side and low side of the system using large-diameter hoses that are as short as possible. When possible, connect the vacuum pump to the system or gauge set using multiple hoses. Figure 30-6 shows a vacuum pump that allows multiple connections between the vacuum pump and the system being evacuated. Removing Schrader valve cores using a vacuum-rated valve core tool will also decrease the time required for evacuation.

Figure 30-6 The Appion TEZ8 vacuum pump has multiple connectors, allowing several hoses to be connected at one time. (Courtesy of Appion Inc.)

Desired Evacuation Level

The lower the final system evacuation level is, the better. Lower evacuation levels give more assurance of a dry system. However, the actual evacuation level required to vaporize all the water in the system is dependent on temperature. Lower system temperatures require lower levels of evacuation to ensure a dry system. Figure 30-7 shows that at an absolute pressure of 400 microns, water will vaporize at temperatures as low as -20°F . A system pressure as high as 1,100 microns will vaporize water at 0°F . The most common benchmark for a good vacuum is a system pressure no higher than 500 microns. Generally, a system is considered to be dehydrated if the system can hold a pressure of 500 microns or lower. Components with refrigeration oil cannot be evacuated lower than 200 microns, because the oil starts to produce a vapor pressure at 200 microns.

Outgassing

Under deep vacuum, many materials release a small number of molecules that create a slight vapor pressure. This is known as outgassing. Vacuum levels below 500 microns are difficult to maintain due to outgassing of connection hoses and materials in the refrigeration system. Refrigeration hoses do this more when they are new. Although many vacuum pumps are available that can pull down below 50 microns, it is not practical to evacuate most system components to this level in the field due to outgassing.

Keeping Water out of System

It saves a great deal of time to follow good refrigeration practices when assembling systems. This includes keeping system components and piping plugged or capped while awaiting assembly and storing components with a charge of dry nitrogen to discourage the entry of air and moisture (Figure 30-8). One of the principle components of air is moisture; letting in air automatically lets in moisture as well. Allowing air in on a hot, humid day allows a significant amount of moisture in. If the component is stored on a cool location, water that came in as water vapor on a warm day may condense to droplets of liquid water, which will significantly increase the time required for system dehydration.

It is far easier to keep moisture out of a system in the first place than it is to remove it.

30.8 VACUUM PUMPS

Two general designs of vacuum pumps are available: rolling piston (Figure 30-9) and rotary vane (Figure 30-10). Reciprocating-piston-type pumps are not used as vacuum pumps. They are incapable of producing a deep vacuum because of the clearance necessary between the piston head and valve plate. The rolling-piston or the rotary-vane designs are more suited for deep vacuum because neither requires any clearance volume. The rolling-piston type is capable of lower pressures and is more rugged. However, these pumps are also much heavier and more expensive

Figure 30-10 Rotary-vane vacuum pump.

Figure 30-11 Rolling-piston vacuum pump.

Figure 30-12 Rotary-vane vacuum pump. (Courtesy Ritchie Engineering Company, Inc., Yellow Jacket Products Division)

(Figure 30-11). Most refrigeration vacuum pumps are rotary-vane-type pumps (Figure 30-12). These have the advantage of being lightweight and relatively inexpensive.

Vacuum pumps are produced in single-stage and two-stage models. Single-stage pumps discharge directly to the atmosphere (Figure 30-13). Two-stage pumps have a first stage that discharges into the suction side of the second stage (Figure 30-14). Two-stage pumps generally have the best record in the refrigeration industry. They are capable of producing consistently lower pressures and are generally more efficient when removing water vapor.

Gas Ballast Valve

A problem with two-stage pumps is that there is a slight compression of the discharge gas coming out of the first stage and entering the second stage. This can tend to condense the water vapor being removed from the system and

Figure 30-13 Single-stage vacuum pump.

Figure 30-14 Two-stage vacuum pump.

leave it in the vacuum pump oil. To prevent this problem, the discharge of the first stage can be directed out to the atmosphere instead of into the second stage through a valve known as a gas ballast valve. This limits the vacuum that the pump can produce, since admission of outside air will raise the absolute pressure of the second stage. The gas ballast valve is typically only open during initial pulldown and is closed once the system pressure has dropped to 20 in Hg vacuum (Figure 30-15).

Isolation Valve

Most vacuum pumps have valves that shut off the pump from the connections to the pump (Figure 30-16). These valves can be used to valve off the vacuum assembly from the vacuum pump. This valve should be shut off before turning the pump off. If the valve is left open, the vacuum in the system can suck the oil in the pump out of the pump and

into the hoses, vacuum gauge, or even the system if left open long enough. The valve should be left closed when the pump is not in use to prevent contamination of the oil in the vacuum pump.

Vacuum Pump Ratings

Vacuum pumps have two ratings: a volume capacity and a blank-off pressure. The volume rating tells how fast the pump can move gas at ideal conditions. Rotary-vane vacuum pumps intended for refrigeration use are available with capacities from 1 CFM up to 12 CFM. The CFM rating tells how many cubic feet of gas the pump can move in 1 minute at ideal conditions. Figure 30-17 shows the suggested maximum system size for different CFM vacuum pumps.

The blank-off pressure tells the lowest pressure the vacuum pump can produce. For refrigeration use, the vacuum pump blank-off pressure should be no higher than 50 microns. The blank-off pressure is more important to pulling a good vacuum than the CFM rating. Once the initial outrush of gas has been accomplished, the speed of evacuation has more to do with the pressure difference between the system and the vacuum pump. The lower the pump's blank-off pressure, the greater this final pressure difference will be. A 1-CFM pump with a 15-micron blank-off pressure will evacuate most systems more quickly than a 10-CFM pump with a 100-micron blank-off pressure.

30.9 VACUUM PUMP OIL

The oil in a vacuum pump acts as a seal as well as a lubricant for the pump. A vacuum pump cannot pull a vacuum any lower than the vapor pressure of its oil. Oil that is not intended for use in vacuum pumps has a much higher vapor pressure than vacuum pump oil and will limit the amount of vacuum the pump can produce. Likewise, dirty oil will do the same thing. All the gases pulled out of a system by the vacuum pump pass through the vacuum pump oil. Refrigerant, water, and acids will dissolve in the oil as they pass through. Contaminants dissolved in the oil will produce a vapor pressure and limit the pump's ability to pull a good vacuum. Clean vacuum pump oil is typically clear (Figure 30-18). Vacuum pump oil that is contaminated with a large amount of water is milky or cloudy in appearance (Figure 30-19). Leaving dirty oil in a vacuum pump also exposes its internal parts to potentially corrosive chemicals, reducing its useful life. To maintain peak performance and prolong equipment life, most vacuum pump manufacturers recommend replacing the oil in the pump after each evacuation. One vacuum pump has a unique design that allows the oil in the vacuum pump to be changed while the pump is operating. The majority of the oil is kept in a clear outboard canister that can be swapped out. The oil is changed by removing the old oil canister and putting in a new one (Figure 30-20).

Figure 30-18 The oil sight glass in a vacuum pump should show clear, clean oil.

Figure 30-19 Cloudy or milky vacuum pump oil is contaminated with water.

Figure 30-21 The vacuum scale on compound gauges is calibrated in Hg vacuum.

The amount of volatile contaminants in the oil can be tested with a vacuum gauge. A vacuum pump should be able to pull down to 50 microns when connected directly to a vacuum gauge if it is in good shape and the oil is clean.

30.10 VACUUM GAUGES

The compound gauge used on most gauge manifolds has a vacuum scale that reads from 0 psig down to 30 in Hg vacuum (Figure 30-21). However, mechanical gauges cannot accurately indicate the difference between a poor vacuum and a great vacuum. The needle on the gauge is typically wider than the space occupied by 1 in Hg vacuum (Figure 30-22). A high vacuum gauge is required for accurate vacuum readings, and the industry has developed electronic instruments to measure high vacuums.

Figure 30-22 The needle thickness is equal to the space occupied by 1 in Hg vacuum on the compound gauge.

Figure 30-23 Thermistor sensor used with electronic vacuum gauge.

In general, electronic vacuum gauges are heat-sensing devices. The element that is connected to the system generates heat. The rate at which the heat is carried off changes as the surrounding gases and vapors are removed. The output of the sensing element changes as the heat dissipation rate changes. This output is indicated on a meter that is calibrated in microns. The sensors used in these instruments are typically either a thermocouple or thermistor (Figure 30-23). Three general styles of electronic vacuum gauges are available:

- Vacuum gauges with an analog scale and needle (Figure 30-24)
- Vacuum gauges with a digital numeric display (Figure 30-25)
- Vacuum gauges with lights or segments that indicate general vacuum levels (Figure 30-26)

30.11 MAINTAINING VACUUM GAUGE ACCURACY

A deep vacuum gauge is really only useful if it is accurate. To maintain accuracy, the manufacturer's instructions and specification must be followed. Conditions that can lead to

Figure 30-24 Analog electronic vacuum gauge. (Courtesy Robinair)

Figure 30-25 Electronic vacuum gauge with digital readout.

Figure 30-26 Segmented digital vacuum gauge. (Courtesy of Robinair)

inaccurate readings or damaged vacuum sensors include failure to calibrate the vacuum gauge, getting the sensor dirty, and exposing the vacuum gauge to high pressures.

Vacuum Gauge Calibration

Most analog vacuum gauges require calibrating before using. To calibrate the gauge, turn it on while the sensor is reading atmospheric pressure. Adjust the calibration screw until the needle indicates atmospheric pressure (Figure 30-27).

Figure 30-27 Analog vacuum gauges should be calibrated to atmospheric pressure before use.

Most digital vacuum gauges sold today do not require calibration when used. However, a quick way to check the accuracy of a vacuum gauge is to turn it on while it is exposed to atmospheric pressure. The gauge should not indicate a vacuum but should read atmospheric pressure. Segmented gauges typically have a segment at the top that indicates atmospheric pressure (Figure 30-28). Gauges with digital numeric displays typically show a single “1” to indicate atmospheric pressure (Figure 30-29).

Next, connect the gauge to a vacuum pump using as little connection hose as possible. Operate the pump. The vacuum gauge should read no higher than 50 microns. This is also a means of testing the pump. A pump with dirty oil will not pull down to its normal blank-off pressure. These two tests help demonstrate that both your vacuum gauge and pump can perform their jobs.

Cleaning the Vacuum Sensor

Most vacuum sensors will not read accurately if they become dirty or contaminated with refrigeration oil. They may normally be restored to proper working condition by cleaning them using alcohol. After cleaning, turn the gauge upside down and allow the vacuum sensor to dry for 20 to 30 minutes before using the gauge.

Figure 30-28 Segmented vacuum gauge showing atmospheric pressure.

Figure 30-29 Digital vacuum gauge showing atmospheric pressure.

SERVICE TIP

Do not attempt to clean the vacuum sensor by sticking Q-tips, wires, small screwdrivers, or any other crude device into the sensor. The chance of destroying the sensor this way is far greater than the chance of improving it.

Figure 30-30 The 1/4-in center port on a four-port manifold can be used to connect a vacuum gauge.

Maximum Pressure

Never expose the vacuum sensor to pressures higher than its rating. Check with the vacuum gauge manufacturer to determine the sensor's maximum pressure rating. Some vacuum sensors are designed to withstand pressures as high as 400 psig, but the sensors used with some vacuum gauges are not able to withstand high pressures. To avoid damaging these sensors, a shutoff valve should be used between the sensor and the system so that the sensor may be isolated from the system before it is pressurized. This may be accomplished by connecting the vacuum gauge to the 1/4-in center port on a four-port manifold gauge set (Figure 30-30).

30.12 CONNECTING VACUUM GAUGES

The best place to connect a vacuum gauge is directly to the system being evacuated. The vacuum in the system will not be quite as low as the vacuum in the pump. Measuring vacuum at the system ensures accuracy. To connect a vacuum gauge directly to the system, either a third system access port is necessary or an adapter that allows connection of both the vacuum sensor and a charging hose to a single port can be used. A short hose or coupler is usually necessary to connect the vacuum sensor to the valve port because the connection on most vacuum gauge sensors is exactly the same as most service valve ports, 1/4-in male flare. The ideal connection is a short metal coupler (Figure 30-31).

Commercial refrigeration systems frequently have three service ports: one on the suction side of the compressor, one on the discharge side of the compressor, and one on the liquid receiver. The vacuum gauge can be connected to the discharge service valve port while the vacuum is drawn from both the suction service valve and the king valve (Figure 30-32). Heat pumps typically have a

Figure 30-31 The vacuum gauge can be connected directly to the system using a short metal coupler or metal hose if the system has more than two gauge ports.

third access port that is always on the suction side of the compressor. The vacuum can be drawn through the common suction port and the liquid-line port while the vacuum gauge is connected to the large gas-line port (Figure 30-33).

Blank-Off Valves

Many systems have only two service ports. Using a blank-off test valve allows connection of both the vacuum sensor and charging hose directly to the system. The built-in shut-off valves allow the vacuum sensor to be isolated from the system before it is charged.

Vacuum Manifolds

Another way to connect the vacuum gauge to the system is to use a vacuum manifold. A vacuum manifold is a device for connecting a vacuum sensor to both the system and the vacuum pump. Manifolds like the ones shown in Figure 30-34 attach to

Figure 30-32 The vacuum gauge can be connected to the discharge service value on commercial systems that have king valves.

the vacuum pump and allow the connection of two $\frac{3}{8}$ -in vacuum hoses as well as connection of the vacuum gauge. One problem with a vacuum manifold that connects to the vacuum pump is that the vacuum is being read at the pump instead of at the system.

Figure 30-34 A vacuum manifold can be used to allow connection of multiple hoses and a vacuum gauge at the vacuum pump. (Courtesy of Ritchie Engineering Company, Inc., Yellow Jacket Products Division)

Schrader Valves

Most residential systems have Schrader valves for service ports. The core in a Schrader valve is a significant restriction and increases the amount of time required to evacuate and charge a system. Figure 30-35 shows a cutaway of a Schrader valve with a core in it. Valve core removal tools with side ports, like the one shown in Figure 30-36, can be used to remove Schrader cores during evacuation and charging and to replace them when charging is complete. This can cut the evacuation time in half. Be sure to use a vacuum-rated core tool to prevent introducing air into the system during evacuation.

Figure 30-35 Schrader valve cores offer a great deal of restriction to evacuation and charging.

Figure 30-36 A valve core tool with a side port can be used to remove the valve core during evacuation and charging.

Care should be used when removing and replacing valve cores during routine service because Schrader valves are not designed to have their cores removed and replaced frequently. It is possible to damage the Schrader valve, making it necessary to recover the system refrigerant and replace the damaged Schrader valve.

SERVICE TIP

Most manifold gauge sets have an internal opening and hoses with $\frac{1}{4}$ -in diameter. Larger gauges and hoses are available that have a $\frac{3}{8}$ - or $\frac{1}{2}$ -in interior diameter. The larger the interior diameter and the shorter the hose, the faster a system can be evacuated. As the pressure in the system drops, the rate of withdrawal is significantly hampered when working with the smaller-diameter hoses. For most residential applications, this time is not a major problem. However, for larger commercial installations it can become a significant factor in the overall job time. Many manufacturers of gauges provide these larger-diameter hoses, and frequently they are black in color and less flexible than the normal-gauge hoses.

Figure 30-37 The cross-sectional area of a $\frac{3}{8}$ -in hose is over twice that of a standard $\frac{1}{4}$ -in hose, allowing faster evacuation and charging.

30.13 DEEP EVACUATION

The deep-vacuum method is the most positive method of ensuring a system free of air and water. The equipment required includes a vacuum pump with a blank-off pressure no higher than 50 microns, a reliable electronic vacuum gauge, a gauge manifold or vacuum manifold, and all connecting hoses. Hoses should be as short as possible and connections should be kept to a minimum. Use $\frac{3}{8}$ -in or larger hoses whenever possible (Figure 30-37).

The actual physical connection used depends very much upon the tools and equipment. The vacuum gauge can be connected directly to the system and the vacuum pump connected to the middle port of a standard three port manifold gauge on systems with three access valves, as in Figures 30-32 and 30-33. Figure 30-38 shows a connection using a standard three-port manifold with the vacuum gauge connected to the heat pump permanent suction service port. Figure 30-30 shows a connection using a four-port manifold with the vacuum gauge connected to the $\frac{1}{4}$ -in center port and the vacuum pump connected to the $\frac{3}{8}$ -in center port.

These are only a few of the possible connection strategies. Regardless of how the vacuum pump and gauge are connected, the technician should keep in mind a few overall concepts.

- There should be no pressure in the system before connecting a vacuum pump. If there is still refrigerant in the system, it must first be recovered before attempting to pull a vacuum. If the system is pressurized with nitrogen, release the nitrogen before beginning evacuation.
- The vacuum level must be measured with an accurate vacuum gauge. Mechanical gauges are not accurate

Figure 30-38 Vacuum pump and vacuum gauge connections using standard three-port manifold and a third system gauge port.

enough to determine when a system has been properly evacuated.

- The vacuum integrity of the connections should be checked before evacuating the system.
- The system should be evacuated from both the low side and the high side simultaneously.
- The system should be able to be isolated from the vacuum pump upon completion of the vacuum.
- The vacuum gauge should be able to read the system pressure during a blank-off period at the end of the vacuum.
- The vacuum gauge should be able to be isolated from system pressure during charging.
- After pulling the system down to under 500 microns, valve it off and wait to see if the vacuum level will hold.
- A continuous, rapid rise in pressure indicates leaks either in the system or in the evacuation connections.
- A slow rise that levels off between 1,500 and 5,000 microns indicates system contamination with water.
- If the system leaks, the leaks must be identified and repaired. If the system is contaminated with water, further evacuation should correct the problem.

Whenever possible, check the vacuum integrity of your connections before evacuating the system. This can be done with manual service valves by making all connections and opening all valves except the system service valves. The vacuum pump should be able to pull below 500 microns quickly on the vacuum setup. If it cannot, then you are wasting your time trying to pull the system under 500 microns. To improve vacuum integrity, use as few mechanical connections as possible, and use short, low permeation hoses.

How Long Should It Take to Pull a Deep Vacuum?

The simple answer is that there is no specified period of time that is required for a deep vacuum. A deep vacuum is done when the system pressure will hold below 500 microns (Figure 30-39). A deep vacuum can be pulled on small, dry systems in minutes. The lines and evaporator coil on

Figure 30-39 The system should be evacuated to under 500 microns for a deep vacuum.

new installations of residential air-conditioning split systems can typically be thoroughly evacuated to under 500 microns in 30 minutes. However, the same system with water contamination may take several hours. Time is not a replacement for a vacuum gauge. Pulling a vacuum all weekend is not an assurance that the system is properly evacuated. If the system leaks, no amount of time will work.

30.14 MULTIPLE EVACUATION

A multiple evacuation is an alternative to the deep-vacuum procedure. Multiple evacuations can be faster than a single deep evacuation. The multiple-evacuation procedure typically does not require a deep-vacuum gauge. Multiple evacuation, sometimes called triple evacuation, is really several short vacuums in succession that are broken in between with dry nitrogen. The nitrogen absorbs and/or dislodges moisture in the system, making it easier to remove on subsequent evacuations. The number of evacuations, the amount of nitrogen introduced between evacuations, and the time given for the nitrogen to “blot up” the moisture varies. There is really no scientific way of knowing how to adjust any of these factors for a particular system. The most common multiple evacuation is the triple evacuation, in which three successive vacuums are used.

Figure 30-40 shows a typical connection for multiple evacuation using a four-port manifold. If there is nothing in the system, it is advisable to put some dry nitrogen in before the first vacuum. This will yield one extra “blotting” period. Dry nitrogen is nitrogen that is free of water. Nitrogen is available in different grades and can sometimes contain water. Be sure when purchasing nitrogen to request dry nitrogen.

TECH TIP

The term *dry nitrogen* is not very well defined. Suppliers use their own names for the grades of gas products they sell. All compressed gas contains some level of other substances. The amount is typically measured in parts per million (ppm). The grade of the gas is indicated with two numbers that describe the percentage of purity. The first digit tells how many “9” digits are in the percentage, and the second digit identifies the number after the last “9.” A grade 5.6 gas is 99.9996% pure. A 3.0 grade, 99.90% pure, is the minimum acceptable for refrigeration purposes. It is important to ask your gas supplier what the gas grade is you are purchasing and what the level of water is in it.

Of course, it is imperative to use a nitrogen regulator and pressure-relief valve when pressurizing the system. Nitrogen tanks hold pressures as high as 2,000 psig, and no refrigeration system will stand up to that kind of pressure. Recommendations on what pressure to use for the blotting period vary from 2 psig to full-test system pressures. For safety, never exceed the low-side system test pressure when adding the nitrogen. Let the nitrogen stand in the system for 10–15 minutes. Blotting times of up to 1 hour are sometimes recommended. However, if you are

Figure 30-40 Connection for multiple evacuation.

going to invest that kind of time, you might as well pull a deep vacuum. Obviously, longer waiting periods will generally yield better results.

Connect the vacuum pump to the center port of your gauges, open both manifold gauge valves, and pull a vacuum from both sides of the system. Let the pump pull for as long as the compound gauge will give you a visible drop in pressure. In any case, do not shut off the vacuum pump until the compound gauge has bottomed out (Figure 30-41). If an electronic vacuum gauge is used, watch how quickly the system pulls down. There may be no advantage in using the multiple-evacuation method if it is possible to achieve a deep vacuum quickly. Pulling a system down three times

to 500 microns is really not any better than pulling it down once if the vacuum holds under 500 microns.

SERVICE TIP

Electronic vacuum gauges are generally not used for multiple evacuations, but using one can easily demonstrate the effectiveness of multiple evacuation. Note the speed with which the unit pulls down on each successive evacuation. Generally, the system pulls down faster with each sweep.

Figure 30-41 The compound gauge should peg out at 30 in Hg vacuum with each evacuation on a multiple evacuation.

UNIT 30—SUMMARY

The only two chemicals that should be circulating in a refrigeration system are refrigerant and oil. Contaminants such as moisture and noncondensable gas reduce system capacity and shorten the life of system components while increasing the system operating cost. Evacuating a system ensures that the system is free of noncondensables and moisture before charging. Deep vacuums are measured in microns using electronic vacuum gauges. The lower the number, the better the vacuum; a deep vacuum should hold under 500 microns. Micron vacuum gauges are used to measure deep vacuum. The vacuum scale on a compound gauge is not accurate enough to read a deep vacuum. The best place to connect the vacuum gauge is directly to the system. Systems should be leak tested before evacuation to avoid introducing contaminants and wasting time. To speed up evacuation use short, large-diameter hoses.

WORK ORDERS

Service Ticket 3001

Customer Complaint: System Is Tripping Main Circuit Breaker

Equipment Type: R-22 Residential Split System

The service technician checks to make sure the thermostat and compressor disconnect are turned off. Then the technician checks to make certain the breaker is good and turns power on to the disconnect. Leaving the disconnect off, the technician checks and determines the compressor is grounded. The technician reports to the customer that the compressor is bad, and the customer wants the compressor replaced.

The technician checks the price book and provides the customer with a cost estimate for the job. The customer accepts the estimate, and the technician calls the office and has the parts department send a replacement compressor.

While the compressor is being delivered, the technician puts on safety glasses and gloves and proceeds to recover the refrigerant. After the refrigerant is recovered to the proper level, the technician replaces the compressor and installs the liquid- and suction-line driers. A leak test is then performed to verify a tight system.

With a leak-free system, the technician then evacuates and dehydrates the system to 500 microns. After determining the system is tight and dry, the refrigerant-charging process is started. To ensure the efficiency and longevity of the system, this process should be performed to the manufacturer's specifications.

After the technician cleans up all of the packaging and other scrap material from the worksite, the customer is provided with a service ticket.

Service Ticket 3002

Customer Complaint: Poor Cooling and High Operating Cost

Equipment Type: R-22 Split System, New Condensing Unit Replacement

A customer complains that his new air conditioner does not seem to cool as well as his old one did and costs more to operate. The technician checks the system pressures and finds that the high-side pressure is 50 psig higher than the manufacturer's specification. The compressor is very hot, the compressor amp draw is high, and the system superheat is 30°F, but the unit calls for 15°F. The technician recognizes that this is not a simple case of overcharge because of the high superheat. The technician asks the homeowner for more information about the installation, and the homeowner confesses that a friend of his changed the unit out one day during an extended lunch break. The technician suspects that the system has noncondensables from not being thoroughly evacuated. All the refrigerant is recovered into a

separate cylinder. The system is evacuated to under 500 microns and a new charge of clean refrigerant is weighed in. The technician runs the system until all the pressures and temperatures stabilize and then checks the system pressures and superheat. The system now is operating at the required 15°F superheat with a normal condensing pressure. The compressor is running cooler and the amp draw is down under the data plate current rating.

Work to Be Performed: New System Startup

Equipment Type: R-410A Split-System Air Conditioner

A technician is called to perform a new system startup on an R-410A split system. The technician notices that the installing technician did not install a liquid-line filter drier. The start-up technician explains that the system has POE lubricant and requires a filter even on new installations because of the hygroscopic nature of POE. He installs a new liquid-line filter drier and tests the lines for leaks using dry nitrogen. There are no leaks, so he releases the nitrogen to the air. The technician connects his gauges to both sides of the system and connects his vacuum pump to the large vacuum hose connected to the 3/8-in port on his gauges. A vacuum gauge is connected to the low side of the system using a vacuum shutoff valve that allows connection of both the low-side hose and the vacuum gauge. The technician turns on the vacuum pump and lets it pull while he completes his visual inspection and other system checks. When he has completed his other checks he looks at the vacuum gauge and sees that the system has pulled down to 350 microns. He valves off the vacuum pump and waits to see if the vacuum will hold. It does, so he isolates the vacuum gauge by closing the valve on the vacuum shutoff valve, closes the gauge manifold valves, and opens the unit-installation valves by turning them counterclockwise. The refrigerant shipped in the condensing unit fills the lines and coil. Last, the technician operates the system and checks the system charge using the manufacturer's charging chart.

Work to Be Performed: Evacuate System After Repair

Equipment Type: R-134a Commercial Refrigeration Walk-in Cooler

A technician has repaired a leak in a commercial refrigeration system, installed a new filter drier, and checked the system for leaks using dry nitrogen. He is preparing to evacuate the system before recharging it with new, clean refrigerant. Before connecting his gauges, the vacuum pump, and the vacuum gauge to the system, he connects his vacuum gauge directly to his vacuum pump to check the operation of the pump and gauge. The vacuum drops slowly to around 1,500 microns and then

levels off. The technician looks in the oil sight glass and notices that the oil is milky. He knows that contaminated oil can prevent a good vacuum, so he changes the oil in his vacuum pump with clean vacuum pump oil. Again he performs the test, and this time the vacuum drops quickly to 100 microns and then slowly drops to 50 microns. He now proceeds to connect his high-side gauge to the king valve, the low-side gauge to the suction service valve, the vacuum gauge to the discharge service valve, and the vacuum pump to the middle hose. He opens both manifold valves and puts the system service valves at mid-position. He operates the vacuum pump until the vacuum on the system reads below 500 microns. He then closes his manifold valves and back-seats both the king valve and the suction service valve to see if the vacuum will hold. It holds, indicating the system is clean and tight. The technician back-seats the discharge service valve to isolate the vacuum gauge, connects a cylinder of refrigerant to the middle hose, and purges just the middle hose. He back-seat cracks the king valve and weighs in the correct refrigerant charge as liquid into the liquid receiver.

UNIT 31

Refrigerant System Charging

OBJECTIVES

After completing this unit, you will be able to:

1. explain how to determine the correct amount of charge for a split system.
2. discuss the difference between liquid charging and vapor charging.
3. explain how to charge systems that use zeotropic refrigerants.
4. determine the correct superheat for a fixed-restriction air-conditioning system using a superheat charging chart.
5. determine the correct subcooling for a thermostatic expansion valve air-conditioning system using a charging chart.
6. list the variables that affect system operating pressures.
7. define the AHRI standard equipment rating condition.

31.1 INTRODUCTION

There are many outside influences—such as low evaporator airflow due to dirt, improper fan speed, or poor duct design—that can mimic the pressure readings of an undercharged system. Likewise, condenser coil conditions can result in pressure readings that might initially indicate an overcharge. It is, therefore, important that technicians do a thorough job of checking pressures, temperatures, and current draw of systems to determine system charge and performance.

The level of refrigerant charge is a delicate balancing act because both too little and too much refrigerant reduce the system's performance. Overcharging can cause liquid to flood back to the compressor, leading to compressor failure. Overcharging will also cause liquid refrigerant to back up in the condenser, increasing the operating head pressure and reducing system efficiency.

Undercharging can reduce oil return back to the compressor, cause high compression ratios, and lead to compressor overheating. Undercharged systems operate inefficiently due to the increased compression ratio and reduced refrigerant flow.

It is important that the technician understand and employ the evacuation and charging methods recommended by the equipment manufacturer for any piece of equipment. High-efficiency and low-maintenance costs can be ensured by following thorough evacuation and charging procedures.

31.2 LEAK TESTING

Refrigeration systems should always be checked for leaks whenever they need charging. Leak tests should always be performed before evacuating and charging a new system. Checking for leaks prior to evacuation and charging saves time and refrigerant. It is necessary to check for leaks whenever refrigerant must be added to an existing system. Refrigerant does not get used up, so a system that is low on charge has a leak. Just adding refrigerant without finding and repairing the leak costs the customer money, and the system operates inefficiently, using more energy to produce less cooling.

31.3 DETERMINING SYSTEM CHARGE

Whether the system is a new one or an existing one that has been repaired, the final step in putting the system in operation is to charge it with refrigerant. The amount of refrigerant charge is more critical in some systems than in others. Systems that have a receiver and thermostatic expansion valve (TEV) are less critical since extra refrigerant can be stored in the receiver, and the expansion valve feeds the refrigerant into the evaporator as required to match the load.

Any excess refrigerant in systems that do not have a receiver will be stored in some part of the system where it reduces the effectiveness of that part and reduces the capacity of the system. If the system is short of refrigerant, the metering device is not supplied with a solid stream of liquid refrigerant and the evaporator will be starved for refrigerant, reducing the capacity of the system. If the system is overcharged, excessive pressures and floodback to the compressor may damage the compressor. The equipment installation instructions will provide the installer with the correct charging procedure for that piece of equipment. Many equipment manufacturers provide charging information on the equipment access panels (Figure 31-1).

Packaged Units

One way to determine the proper charge is to read it on the name plate, as shown in Figure 31-2. Most manufacturers specify the type and amount of charge on the system data plate. For any one-piece system, such as appliances, window units, or packaged air conditioning systems, the amount on the data plate will be the correct charge.

Split Systems

The amount of charge required for a split system is affected by the length of the refrigerant lines. The length of the refrigerant lines is determined by the conditions of the installation. This is why the correct system charge will be different from one split system to another, even for identical equipment. The condensing unit on a split system has

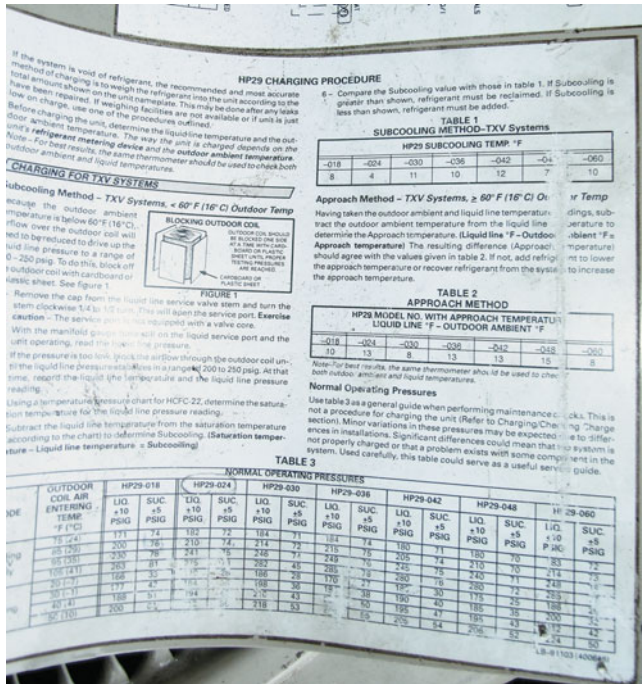

Figure 31-1 Most manufacturers provide charging information inside the unit service panel.

a factory charge amount on the data plate (Figure 31-3). Typically this amount includes enough refrigerant for the condensing unit, the evaporator coil, and some predetermined length of refrigerant line. The assumed line length varies from 15 to 30 ft, depending upon the manufacturer.

Figure 31-3 The factory charge for this split-system condensing unit is shown on the data plate.

Figure 31-4 Many manufacturers provide details on adjusting the charge for line length inside the system service panels.

Liquid Line Size	R-22 or R-410A (oz/ft)
1/4	0.4
3/8	0.6
1/2	0.8
5/8	1.0

Figure 31-5 Liquid-line allowance table.

The assumed line length used for any particular piece of equipment can be found in the installation instructions or on the inside of the service access panel (Figure 31-4).

The system charge must be adjusted if the actual line length varies from the assumed line length. Most manufacturers only compensate for the liquid line and not the suction line because the amount of refrigerant in the suction line is so slight. Figure 31-5 shows how much refrigerant to add or subtract for every foot of difference in line length. This remains the same regardless of the type of equipment because it is based on the physical volume of the different size liquid lines. For example, a system with a factory charge of 56 oz of R-410A, an assumed line length of 15 ft, and a 3/8 in liquid line that is 35 ft long.

$$56 \text{ ounces} + (35 - 15) \times 0.6 \text{ oz/ft} = 56 \text{ oz} + 12 \text{ oz} = 68 \text{ oz total system charge}$$

Repairing Existing Equipment

When the system charge has been recovered to repair an existing system, the total system charge should be weighed in after evacuating the entire system.

New Installations

For new split-system installations, only the additional amount of charge needs to be determined and added because the condensing unit comes precharged. In the above example, only 12 oz needs to be added for a new installation. The procedure for charging a new split system would be as follows:

- Install refrigeration lines and evaporator coil.
- Evacuate the lines and coil below 500 microns.
- Determine the amount of charge adjustment needed for the extra line length.
- Weigh the charge adjustment into the evacuated lines.
- Open the charging valves on the condensing unit.

SERVICE TIP

Too often, technicians in the HVACR field are of the opinion that if a little refrigerant is good, a lot is better, and too much is just about right. Refrigerant is not a magical fluid that adds cooling capacity to a system. The cooling capacity of a system that is overcharged is significantly decreased. The only time a system will operate with its designed peak performance is when the charge is at the manufacturer specified level. It is not an acceptable practice to add just a little more in case the system leaks.

31.4 CHARGING BY WEIGHT

The most difficult aspect of refrigerant charging is not putting refrigerant into a system but knowing when to stop putting it in. There are so many variables to take into account that charging to a particular operating condition can be difficult. The easiest way to have confidence in the charge is to weigh in the correct amount of refrigerant into a fully evacuated system using an accurate scale. Scales such as the one shown in Figure 31-6 can be used to accurately weigh the refrigerant into the system. An electronic scale with the ability to be zeroed with the refrigerant cylinder on the scale is preferred.

Most fully evacuated systems will take in the entire charge in liquid form in one shot. Figure 31-7 shows the setup for weighing liquid into the high side of an evacuated system. To weigh in a system charge after evacuating a system:

Figure 31-6 Electronic charging scales like this one can be used to weigh in a refrigerant charge.

Figure 31-7 Connections for weighing liquid refrigerant into the high side of a system.

- The system should be off and evacuated with the manifold gauges connected to the high and low sides of the system and the manifold valves closed.
- Connect the refrigerant cylinder to the middle hose on the gauges.
- Purge the center hose with vapor from the cylinder while it is in the upright position.
- Do not attempt to purge the other hoses, as they are in a vacuum and do not need purging.
- Invert the cylinder and place it on the scale with the cylinder valve opened.
- Zero the scale with the cylinder on it.
- Open the high-side manifold valve to allow liquid refrigerant to flow from the cylinder into the system.
- The position of the hoses should not be changed during charging because this can change the weight felt by the scale.
- Close the high-side manifold valve when the desired charge is reached.
- Some refrigerant will be left in the hose to the cylinder. To put this in the system: close the cylinder valve, operate the unit, and crack the low side manifold hand valve.

31.5 LIQUID CHARGING

Liquid charging is always much faster than vapor charging. This is because liquid is far denser than vapor and because taking liquid out of the refrigerant cylinder does not affect the cylinder pressure. The primary disadvantage of liquid charging is that it is easy to overcharge a system when adding liquid refrigerant. Liquid is normally charged into the system in one of two ways: into the high side with the system off or by pulling liquid into the liquid line with the system operating and the king valve front seated.

Liquid Charging—System Off

On smaller systems, liquid charging is usually done with the compressor off. Prior to charging, the system must be leak tested and evacuated. Figure 31-7 shows connections for liquid charging in to the high side with the system off. When the charging is started, the system is under vacuum and the refrigerant cylinder is under pressure, so the refrigerant is pushed into the system due to the difference in pressure. After the system has been evacuated, liquid is introduced

into the high side with the system off. Since the compressor can be damaged by liquid in the suction line, liquid is normally not charged into the low side of a system.

The system pressure rises as the refrigerant enters the system. Sometimes the system pressure and cylinder pressure will equalize before the full amount of refrigerant has been charged into the system. When this occurs, the charge may have to be completed as a vapor charge with the system operating.

Liquid Charging—System Operating

On larger systems, a king valve located between the condenser and the metering device offers a convenient means of charging the system on the high side, with the compressor running. When the king valve is front-seated (Figure 31-8), flow from the receiver is shut off. As the system operates, the pressure in the liquid line leaving the receiver starts to drop. When the pressure in the refrigerant cylinder exceeds the pressure in the liquid line, refrigerant is drawn into the system from the cylinder (Figure 31-9). This same technique may be used for most residential split systems by front-seating the liquid-line charging valve (Figure 31-10).

SERVICE TIP

It is easy to overcharge a small system using this charging method. When adding liquid refrigerant with the system operating, the gauges will show both low-side and high-side pressures, but these pressures tell the technician nothing about the amount of charge in the system. The amount of refrigerant added should always be checked with a scale to guard against overcharging.

Figure 31-8 The king valve stem is turned in all the way clockwise to front-seat it.

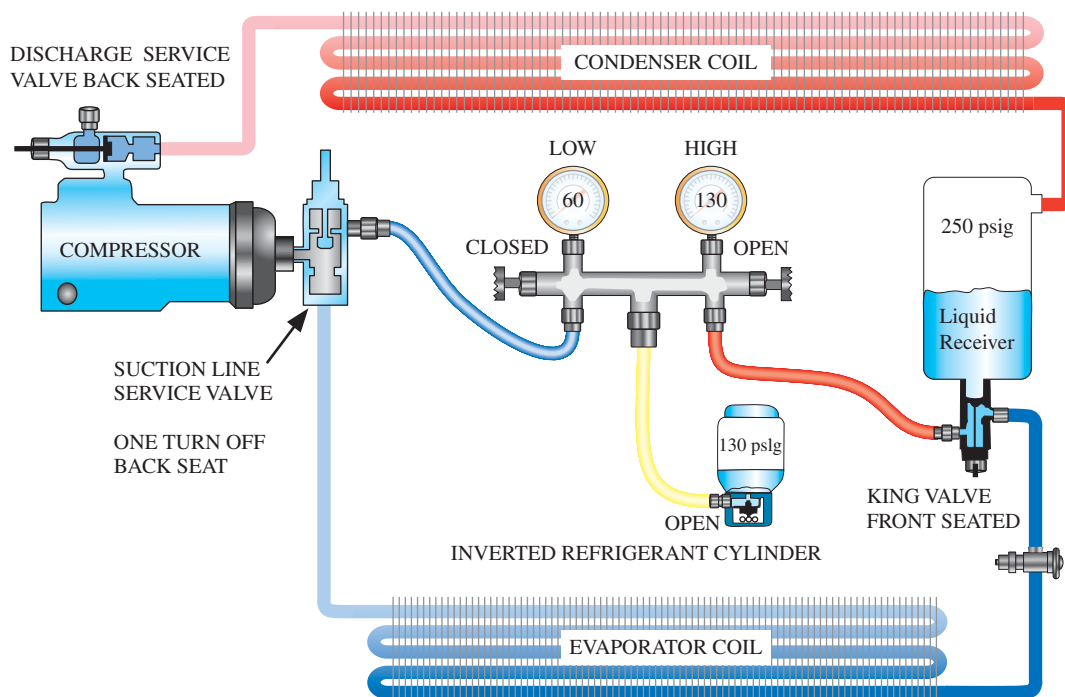

Figure 31-9 With the king valve front-seated and the compressor operating, liquid refrigerant will be drawn into the liquid line.

Figure 31-10 The liquid-line service valve on split-system air-conditioning system can also be used to liquid charge with the compressor operating.

Figure 31-11 King valves that have the gauge port open to the line port when the valve is front-seated can be used for liquid charging with the system operating.

This will not work for all systems that have liquid receivers and king valves! To work properly, the liquid line must be isolated from the liquid receiver and open to the gauge port when the liquid receiver valve is front-seated (Figure 31-11). Many receiver valves isolate the liquid line and leave the gauge port open to the receiver when the valve is front-seated (Figure 31-12). These systems are not candidates for this method! If the liquid line is isolated from the receiver and the gauge port is open to the receiver, high-side pressures from the compressor will be forced into the charging cylinder through the liquid receiver. This condition is very dangerous!

SERVICE TIP

On large systems, liquid charging with the compressor operating and the king valve front-seated may cause compressor overheating and/or low-pressure system shut-down. A system that is normally fed by a 5/8-in liquid line with over 200 psig of pressure cannot be adequately fed by a 1/4-in line with normal cylinder pressure. The result is that the system operates with a starved evaporator and a low suction pressure during the charging process. Liquid charging with the system operating should be limited to short durations of time to avoid system problems.

Figure 31-12 King valves that have the gauge port open to the receiver port when the valve is front-seated should NOT be used for liquid charging with the system operating.

Liquid Charging Chillers

Low-pressure chillers are charged through the evaporator charging valve. Liquid should not be charged into evacuated chillers or units with water-cooled condensers. When liquid is charged into an evacuated unit, the liquid boils at a very low temperature because of the low pressure. This can freeze the water sitting in tubes in evaporators and condensers, causing significant damage to the system. To avoid this, charge the system with vapor until the system pressure is at a saturation pressure equal to 36°F. Liquid may then be safely introduced into the system without fear of freezing the water.

SERVICE TIP

On systems that require large quantities of liquid refrigerant to meet the basic charge requirement, liquid can be pumped into the system by using a cylinder heating band. These bands are thermostatically controlled and sense the cylinder pressure with a pressure-sensitive switch that is connected to the refrigerant charging line. Cylinder heaters can significantly reduce the charging time.

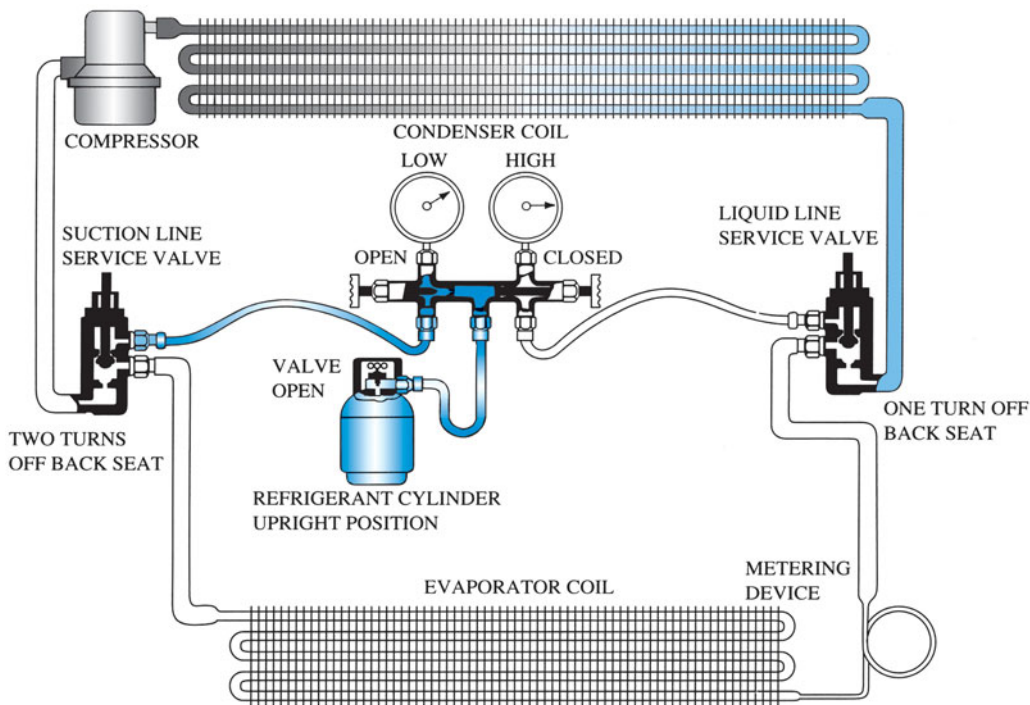

Figure 31-13 Connections for vapor charging a system.

31.6 VAPOR CHARGING

Vapor charging is used to add small amounts of refrigerant slowly because vapor takes up a great deal more space per pound than liquid. When a partial charge is required, vapor charging is usually employed. Figure 31-13 shows a typical connection for vapor charging. The center hose of the gauge manifold is connected to the valve on the refrigerant cylinder with the cylinder in the upright position. The center hose is purged using refrigerant from the cylinder. If the system was evacuated prior to charging, only the center hose needs purging. However, if vapor is being added to a system that already has some charge in it, all gauge hoses should be purged.

SERVICE TIP

Before attempting to vapor charge a system, make sure that the refrigerant to be charged is not a 400 series zeotropic refrigerant, such as R-410A. Zeotropic refrigerants should not be removed from the cylinder as a vapor because they will fractionate and the mixture of refrigerants will be incorrect. Worse, the refrigerant remaining in the cylinder is no longer the correct mixture after fractionation.

Small Appliances

The recommended charging procedure for small appliances whose total system charge is less than a pound is to evacuate the system and introduce vapor into the appliance until the static equalized pressure in the appliance equals the factory specification. This is the most accurate charging method for appliances whose total charge is only a few ounces. This is done after evacuating the appliance with the appliance off.

Refrigerant Cylinder Pressure Drop

The refrigerant cylinder pressure decreases as vapor is drawn out of it, even if there is still plenty of refrigerant left in the cylinder. As the vapor leaves the cylinder, it creates a low-pressure area above the liquid due to the void left by the exiting refrigerant. The liquid in the cylinder boils to fill this void with more vapor. This process continues as long as vapor is being removed from the cylinder. The heat required to vaporize the liquid comes from the liquid refrigerant and the tank itself and leaves with the refrigerant. The result is an ever-decreasing refrigerant temperature. Since the pressure of a saturated refrigerant is determined by its temperature, a drop in temperature also means a drop in pressure. The charging process gradually grinds to a halt because of the drop in cylinder pressure. The frost line on the bottom of the cylinder in Figure 31-14 shows the liquid level of the cylinder. It has been cooled by drawing vapor out of the cylinder.

Figure 31-14 The frost line on this cylinder shows the liquid level; the liquid temperature has dropped because of vapor being removed from the cylinder.

Heating the Refrigerant Cylinder

Heating the refrigerant cylinder will raise the refrigerant temperature and pressure, allowing the charging process to continue. Refrigerant travels from one container to another simply because of pressure difference. A full cylinder of refrigerant with a pressure of 50 psig will not even charge a refrigerator if the pressure in the refrigerator is 50 psig or higher. Remember, the pressure of a saturated refrigerant is controlled by its temperature, not its volume. If both the unit and the cylinder are in a saturated state, there must be a temperature difference to get refrigerant to travel from the refrigerant cylinder into the system. Therefore, heating the refrigerant cylinder is often required during vapor charging.

SAFETY TIP

It is possible to increase the cylinder temperature and pressure to a point where it can rupture and release an awesome amount of energy with one great explosion. Therefore, when a refrigerant cylinder must be heated, these precautions should be taken:

Wait until some of the refrigerant has been removed from a full cylinder before doing any heating.

Never use a concentrated heat form, such as a torch, to heat the cylinder. Warm water or air are effective and safe alternatives.

Limit the maximum temperature exposure of the cylinder to below 125°F.

Never obstruct or tamper with the safety relief device on the cylinder.

Vapor Charging with Unit Operating

Most vapor charging is done with the compressor operating while charging is taking place. The pressure difference between the tank pressure and the system evaporator pressure will be greater if vapor is introduced into the low side while the compressor is operating (see Figure 31-13). This will delay the problem of cylinder pressure drop since the evaporator pressure is lower while the system is operating. If the amount of refrigerant being added is relatively small, operating the compressor and charging vapor into the suction side of the system generally provides enough temperature and pressure difference to complete the charging job. If large quantities of refrigerant are needed, however, the refrigerant cylinder will still have to be heated.

31.7 CHARGING ZEOTROPIC REFRIGERANTS

Refrigerants that fractionate, such as R-410A, must be charged as liquid to prevent the separation of the refrigerant. Weighing a liquid charge into an evacuated system is the same with zeotropes as with regular refrigerant, since the refrigerant leaves the cylinder as a liquid. Adding small amounts with the system operating is different because the refrigerant should not leave the cylinder as a vapor. These re-

frigerants must come out of the cylinder as a liquid but must be a vapor before entering the compressor. To accomplish this safely, the refrigerant must be metered either by the gauge manifold hand valve or by an external charging device.

SERVICE TIP

Most refrigerant cylinders have arrows showing the correct cylinder position for charging. Early R-410A cylinders used a dip tube, so the cylinder delivered liquid in the upright position. Most cylinders used today do not have the dip tube, so they need to be inverted to deliver liquid. Check the arrows on the side of the cylinder to be sure which position the cylinder should be in to deliver liquid.

Zeotropes can be metered in with the unit operating by slightly cracking open the low-side manifold valve and then closing it (Figure 31-15). This allows small amounts of liquid into the low-side hose but gives the liquid time to evaporate before reaching the compressor. Be patient. The liquid must flash off to vapor before entering the compressor. Allowing too much liquid in at once can damage the

compressor because liquid is not compressible! Charging devices like the one shown in Figure 31-16 increase the safety of low-side liquid charging. They are essentially a restriction that acts as a metering device.

Some gauge manifold sets have sight glasses that make it easy to monitor the condition of the refrigerant (Figure 31-17). For gauges that do not have this, a liquid-line sight glass that has $\frac{1}{4}$ -in flare fittings on both ends can be installed in the low-side refrigerant hose.

31.8 FACTORS AFFECTING SYSTEM PRESSURES

Checking the charge on an operating system involves checking some aspect of system performance. The major difficulty in checking system refrigerant charge by measuring any single aspect of its performance is that there are so

Figure 31-17 The refrigerant condition may be monitored using the sight glass in this manifold.

many variables that can affect system performance. Getting all variables that affect system performance to conform to the manufacturer's specifications at one time can be quite challenging. Understanding how each of these variables affects system performance is crucial for the technician trying to measure system performance. Some of the most important variables that can affect system performance include the following.

Outdoor Ambient Temperature for Air-Cooled Units

The high-side pressure on air-cooled systems is largely determined by the outdoor ambient temperature and the amount of air flowing over the condenser. Increased ambient temperature causes increased high-side pressure.

Condenser Airflow for Air-Cooled Units

The airflow across the condenser also affects the high-side pressure. Less condenser airflow means less cooling, causing higher condenser temperatures and pressures.

Inlet Water Temperature for Water-Cooled Units

The high-side pressure on water-cooled systems is largely determined by the condenser inlet water temperature and the water flow. Increased water temperature causes increased high-side pressure; lower water temperature causes lower head pressures.

Condenser Water Flow for Water-Cooled Units

Condenser water flow has a very large impact on high-side pressures in water-cooled units. Reduced water flow means less cooling, causing higher condenser temperatures and pressures. Increased water flow has just the opposite effect.

Return-Air Wet Bulb for Air Conditioners

Return-air wet-bulb (wb) temperature has a big effect on evaporator temperature and pressure in air-conditioning systems. Increased wet-bulb temperatures mean increased heat load on the evaporator, which increases the evaporator temperature and pressure. Low wet-bulb temperatures mean reduced evaporator heat load and reduced evaporator temperature and pressure.

Evaporator Airflow for Air Conditioners

The airflow across the evaporator in an air-conditioning system is critical. Low airflow means low load and lower evaporator temperature and pressure. Reduced airflow also reduces the system sensible cooling (temperature change) while increasing the system latent cooling (removal of water). Increased airflow increases the load on the evaporator and higher evaporator temperature and pressure. Increased airflow increases the system sensible cooling while decreasing the system latent cooling.

Returning Water Temperature for Chillers

Returning water temperature has a big effect on evaporator temperature and pressure in a chiller. Increased water temperatures mean increased heat load on the evaporator, which increases the evaporator temperature and pressure. Lower water temperatures mean reduced evaporator heat load and reduced evaporator temperature and pressure.

Chilled Water Flow for Chillers

The water flow through the evaporator in a chiller is critical. Low water flow means low heat load and lower evaporator temperature and pressure. Reduced water flow can be a hazard for chillers because the water can freeze if its temperature is allowed to drop too low. Increased water flow increases the heat load on the evaporator and increases evaporator temperature and pressure.

31.9 STANDARD INDUSTRY DESIGN AND OPERATION

There are system operating characteristics that have become industry standards through common use. These generic standards should never replace manufacturer information, but understanding what is normal can help a technician understand how all these variables interact with each other.

Standard Design Conditions

The primary rating condition for AHRI-listed unitary air-conditioning equipment is 95°F outdoor ambient and 80°F dry-bulb (db) and 67° wb indoor temperature. Air-conditioning equipment is rated at this condition. Logically, that means this is the ideal operating condition for an air-conditioning system.

Standard Air-Cooled Condenser Temperature

For many years, equipment manufacturers have been designing equipment to operate with a 125°F condenser temperature at the AHRI design condition of 95°F. A reasonably accurate approximation of condenser temperature for older equipment is to add 30°F to the outdoor ambient temperature.

High-Efficiency Air-Cooled Condenser Temperature

Most equipment manufactured today is not designed to operate with a 125°F condenser. Instead, 115°F at 95°F is more common. For newer equipment, condenser temperature can be approximated by adding 20°F to the ambient temperature. It should be noted that there is really an entire range of efficiencies, so the term *approximate* is apt. Some systems now operate as low as 10°F above the ambient temperature.

Water-Cooled Condenser Temperature

Water-cooled condensers typically operate at lower head pressures than air-cooled condensers. Standard design for

water-cooled condensers is 105°F condenser temperature with 85°F entering-water temperature and 95°F leaving-water temperature. This provides two important pieces of information: the difference between the leaving-water temperature and the condenser temperature is approximately 10°F. The temperature rise across the condenser is also approximately 10°F. The condenser temperature of a water-cooled condenser can be approximated by adding 10°F to the leaving-water temperature. Its performance can be quickly checked by looking for a 10°F temperature rise in the condenser water temperature.

Evaporator Temperature in Air Conditioners

The common design for air-conditioning evaporators has been a 40°F evaporator when the air flowing across the evaporator is 80°F and 67°F wb (50 percent relative humidity). Evaporator temperature can be approximated by subtracting 40°F from the return-air temperature. However, this does not account for changes in humidity that will affect the evaporator temperature. Higher wet-bulb temperatures will produce higher evaporator temperatures, while lower wet-bulb temperatures will produce lower evaporator temperatures. The dew point temperature at 80°F db, 67°F wb is 60°F. A more accurate approximation would be to subtract 20°F from the dew point of the return air.

High-Efficiency Evaporator Temperatures

New equipment designed for higher efficiency typically operates at a slightly higher evaporator temperature. Many systems are now designed for 45°F evaporators at the 80°F db, 67° wb condition. This would make the evaporator temperature 35°F colder than the return-air temperature, or 15°F colder than the return-air dew point temperature.

Evaporator Airflow

Standard airflow across an air-conditioning coil is 400 CFM per ton. This is a very commonly applied standard. Many installations tweak this to get the desired amount of sensible and latent cooling from a unit, but practically everyone's unit will work with 400 CFM per ton moving across the evaporator coil.

Evaporator Temperature Drop

The temperature drop across an air-conditioning evaporator is typically around 15°F at the AHRI design of 80°F db, 67° wb. As the wet-bulb temperature drops, the temperature difference increases to a maximum of approximately 20°F. Higher wet-bulb temperatures decrease the temperature drop to a minimum of around 10°F.

Thermostatic Expansion Valve Superheat

Expansion valve superheat settings vary with the design and temperature range of the system. In general, the lower the evaporator temperature, the lower the valve

superheat setting. Low-temperature systems often operate with a valve superheat of 3–5°F, medium-temperature systems with a valve superheat of 5–9°F, and high-temperature systems and air-conditioning systems with a valve of superheat of 9–12°F.

Fixed-Restriction Superheat

The system superheat of fixed-restriction systems varies widely with system operating conditions. At AHRI design conditions, most fixed-restriction systems operate with a superheat similar to expansion valve systems, around 10°F. However, their superheat increases significantly as the outdoor ambient decreases. Subtracting the ambient temperature from 105 gives an approximation of superheat for a fixed-restriction system operating with return air at AHRI design conditions, 80°F db, 67° wb.

Subcooling

The subcooling on most correctly operating refrigeration systems is between 5°F and 15°F. All systems should have some subcooling. Most split systems will have problems with flash gas in the liquid line if they operate at less than 5°F subcooling. Subcooling values exceeding 15°F can be symptomatic of systems that are either overcharged or have a restriction in the liquid line.

31.10 MANUFACTURER CHARGING CHARTS

Some manufacturers provide charging charts, charging calculators, or performance charts for checking the charge while the system is in operation. Some of these performance charts are intended to be used for both checking and adjusting the charge while others are intended only to check system operation.

Figure 31-18 shows a performance chart for an R-410A packaged unit that correlates suction pressure, discharge pressure, and outdoor ambient temperature. Note that this chart requires the indoor temperature to be at comfort conditions (Figure 31-19). If the indoor temperature is outside of comfort conditions, the chart will not be accurate. The liquid pressure is read on the left side of the chart, and the suction pressure is read across the bottom of the chart. Find the intersection of the liquid and suction pressures. This intersection should fall on or near the diagonal line for the outdoor ambient temperature. If the intersection falls above the ambient temperature line, the system is overcharged. If the intersection falls below the ambient temperature line, the system is undercharged.

Figure 31-20 shows examples of undercharged, overcharged, and correctly charged systems operating at an outdoor ambient of 85°F. The dark blue lines represent a correctly charged system with a liquid pressure of 310 psig and a suction pressure of 140 psig. They intersect exactly on the light blue 85°F diagonal ambient temperature line. The red lines show an example of an overcharged system at the same ambient temperature, 85°F. The liquid pressure of 340 psig and the suction pressure of 160 psig intersect above the light blue 85°F diagonal ambient temperature

line, indicating an overcharge. The green lines show an example of an undercharged system at the same ambient temperature, 85°F. The liquid pressure of 290 psig and the suction pressure of 130 psig intersect below the light blue 85°F diagonal ambient temperature line, indicating an undercharge.

31.11 CHARGING FOR PROPER SUPERHEAT

The superheat method is a very accurate means of checking the refrigerant charge. A change in refrigerant charge of 1 percent can change the superheat 3°F. Superheat charging charts are commonly used for systems with fixed-restriction metering devices. This is not as simple as stating a single superheat because the superheat of systems with fixed restrictions fluctuates with operating conditions. Fixed restrictions cannot adjust to varying load conditions, but a change in pressure drop produces a change in refrigerant flow, which produces a change in superheat. Warmer condenser ambient temperatures reduce system superheat by increasing refrigerant flow; cooler condenser ambient temperatures increase system superheat by decreasing refrigerant flow. Return air wet bulb temperature has just the opposite effect. Warmer return-air wet-bulb temperatures will increase superheat; cooler return-air wet-bulb temperatures reduce superheat. Figure 31-21 graphically shows how system operating conditions affect the superheat of systems with fixed-restriction metering devices.

Charging charts like the one shown in Figure 31-22 give the correct system superheat for any operating condition. This can be used to check the system charge at any particular operating condition by comparing the actual system superheat to the superheat specified by the charging chart.

Both the outdoor ambient temperature and the indoor wet-bulb temperature must be known to use the chart in Figure 31-22. Figure 31-23 shows an example with an indoor wet bulb of 66°F and an outdoor ambient temperature of 90°F. Read across from the indoor wet-bulb temperature on the left (66°F) until you reach the column under the outdoor ambient temperature (90°F). The required superheat at this condition is 11°F.

Figure 31-22 This superheat charging chart gives the correct operating superheat based on both ambient temperature and indoor wet-bulb temperature.

*Superheat should never be less than 5°F

Figure 31-21 The degree of superheat required for a correct charge changes in direct proportion to the ambient temperature:

The superheat of an overcharged system will be lower than specified by the charging chart. This is because liquid will be traveling further through the evaporator before it is all boiled off, leaving less evaporator coil to superheat the refrigerant. In this example, a superheat of 7°F would indicate an overcharge. The superheat of an undercharged system will be higher than specified on the chart. This is because the liquid will be completely boiled off early in the evaporator, leaving more of the evaporator to superheat the refrigerant. In this example, a superheat of 15°F would indicate an undercharge.

Make sure to read all the fine print on any charging chart. Manufacturers attempt to make the charging charts

as easy to use as possible while still providing accurate information. Most charts assume something. Typical assumptions would include system airflow, indoor temperature, or indoor humidity. Any condition that is assumed for the sake of simplicity is usually listed somewhere on the chart. Rather than asking for indoor wet bulb, some superheat charts ask for a regular dry-bulb temperature both inside and outside (Figure 31-24). They assume the relative humidity to be 50 percent. These charts will not be accurate if the relative humidity is very far off of 50 percent. Other superheat charging charts only specify an outdoor ambient temperature (Figure 31-25). These charts are assuming an

indoor temperature, usually the AHRI design condition of 80°F, 50 percent relative humidity. These charts are only accurate at this one indoor operating condition.

SERVICE TIP

Be sure to check all system variables, especially the evaporator airflow. Other system variables can cause the superheat to be incorrect. Lower than normal evaporator airflow or a dirty evaporator will cause a low superheat. Higher evaporator airflow can cause a high superheat.

31.12 CHECKING SYSTEM SUPERHEAT

Two measurements are required to check system superheat: the suction line temperature and pressure near the compressor. It is important to use an accurate thermometer, or an electronic temperature probe to take the suction line temperature. Clamp-on thermocouple probes like the one shown in Figure 31-26 work well.

Run the system for 10–30 minutes to allow the temperatures and pressures to stabilize. Also, record the indoor wet-bulb and outdoor ambient temperatures, since these are required in using the manufacturer's charts. Then read the pressure and temperature of the suction line.

Use a pressure-temperature chart like the one in Figure 31-27 to determine the saturation temperature that matches the suction pressure. Subtract the saturation temperature from the actual vapor line temperature to obtain the superheat. Compare it with the manufacturer's recommendation. Most manufacturers allow a variation of $\pm 3^\circ\text{F}$. Add more charge if the system superheat is more than 3°F higher than specified; recover charge if the superheat is more than 3°F lower than specified.

The system must operate for at least 10 minutes after any charge adjustment. Then repeat the test procedure to be certain that the charge is within the proper range.

Figure 31-26 Clamp-style thermocouple temperature testers work well for checking superheat and subcooling.

An R-410a system operating with a suction pressure of 118 psig and a suction line temperature of 51°F has a superheat of 11°F. Using the charging chart in Figure 31-22 and the pressure-temperature chart in Figure 31-27, if these readings are obtained with 90°F ambient and 66°F wb, this system is charged correctly.

31.13 CHARGING FOR PROPER SUBCOOLING

Thermostatic expansion valves (TEVs) will regulate the refrigerant flow over a wide range of load and charge conditions. Because TEVs try to maintain a constant superheat, the superheat method is not the best method for testing the charge in an expansion valve system.

Some manufacturers recommend using subcooling to check the charge on expansion valve systems. Normally, under full load conditions, the refrigerant in an air conditioner will be subcooled 5°F to 15°F leaving the condenser. Figure 31-28 shows a typical subcooling charging chart. The example in Figure 31-29 shows a system operating with an ambient temperature of 95°F and a return-air wet-bulb temperature of 67°F. Read across from the outdoor ambient temperature (95°F) until you reach the column with the indoor wet-bulb temperature (67°F). The subcooling is shown in parentheses. In this example, the required subcooling is 5°F.

An undercharged system will have less subcooling than specified because there is less liquid sitting at the bottom of the condenser. An overcharged system will have a higher subcooling because there will be extra refrigerant sitting in the condenser.

31.14 CHECKING SYSTEM SUBCOOLING

Two measurements are required to check system subcooling: the liquid-line temperature and pressure leaving the condenser. It is important to use an accurate thermometer, or an electronic temperature probe to take the liquid-line temperature. Clamp-on thermocouple temperature probes like the one shown in Figure 31-26 work well.

Run the system for 10–30 minutes to allow the temperatures and pressures to stabilize, then read the pressure and temperature of the liquid line.

Use a pressure-temperature chart like the one in Figure 31-27 to determine the saturation temperature that matches the liquid pressure. Subtract the actual liquid temperature from the saturation temperature on the chart to obtain the subcooling. Compare it with the manufacturer's recommendation. Most manufacturers allow a variation of $\pm 1^\circ\text{F}$. Add more charge if the system subcooling is more than 1°F lower than specified; recover charge if the superheat is more than 1°F higher than specified. The system must operate for at least 10 minutes after any charge adjustment. Then repeat the test procedure to be certain that the charge is within the proper range.

An R-22 system operating with a liquid pressure of 227 psig and a liquid-line temperature of 105°F has a subcooling of 5°F. Using the chart in Figure 31-29, if this system is operating with a 95°F ambient temperature and a 67°F wb temperature, the system is charged correctly.

31.15 LIQUID-AMBIENT APPROACH-CHARGING METHOD

The liquid line is always a little warmer than the outdoor ambient temperature. The approach-charging method examines the temperature difference between the liquid line and outdoor ambient temperature. To calculate the approach, measure the liquid-line temperature and outdoor ambient temperature and subtract the outdoor ambient temperature from the liquid-line temperature. It is a good idea to either use the same thermometer to take both readings or to compare the two thermometers used at ambient temperature to make sure they correspond. Just a few degrees of difference can give a different diagnosis. Compare the measured temperature difference to the manufacturer's specification (Figure 31-30). If the temperature difference is higher than specified, the system is undercharged. If the temperature difference is lower than expected, the system is overcharged.

31.16 WATER-COOLED SYSTEMS

The first checks to make on any water-cooled system are water temperature and flow. The pressures of a water-cooled system operating with too little water flow will be higher than normal, making the system look as if it is overcharged. The pressures of a water-cooled system operating with water that is too cold will be lower than expected, making the system appear to be undercharged. The manufacturer's performance data for water-cooled systems typically specify the condenser water flow, inlet water temperature range, and condenser water temperature rise

31.17 OIL CHARGING

Very rarely does oil need to be added to a refrigeration system. Unlike engine oil, refrigeration oil does not need to be changed regularly. The initial charge of refrigeration oil should last for the life of the system. A refrigeration system is a closed system, free of air and other contaminants. Further, the temperatures inside a refrigeration system are designed to stay under the temperature at which the oil

begins to break down. Leaks seldom release enough oil to warrant adding any. A very small amount of oil sprayed out with refrigerant vapor makes a large, oily spot that may appear to be evidence of a large oil leak. When the compressor is low on oil, the oil is usually just somewhere else in the system. However, there are times when it is necessary to remove or add refrigeration oil.

Checking Oil Level

On compressors that have a crankcase sight glass, as in Figures 31-32 and 31-33, the correct oil level can be accurately observed and the quantity adjusted to the level indicated in the sight glass. It is important, however, to observe the oil level after the system has been in operation. Refrigerant will

Figure 31-33 Dissolved refrigerant raises the oil level during the off cycle.

Figure 31-34 The oil level starts out too high, drops too low shortly after startup, and settles at the correct operating level after several minutes of operation.

dissolve in the oil during system shutdown and raise the apparent oil level. This refrigerant boils out when the system starts, carrying some of the oil with it. Most of this oil returns after the system has operated long enough for the pressures to stabilize, but some oil remains in the system all the time. The typical level in an oil sight glass starts out above the normal oil level, drops to the bottom of the sight glass shortly after startup, and then gradually rises to the normal operating level (Figure 31-34). If the oil level is low after the system pressures have stabilized and the compressor crankcase is warm, the system may be low on oil.

Changing Compressor Oil

Oil is a scavenger, and it will end up collecting most of the crud in a system. One of the fastest ways to clean a system that has experienced multiple compressor failures is to check and change the compressor oil. Occasionally, refrigeration oil needs to be changed to make a refrigerant retrofit possible because the new refrigerant does not work well with the old refrigeration oil. Changing refrigeration oil for any reason is only really possible in systems with semihermetic or open compressors.

Hermetic Compressors

It is not practical to remove oil from a hermetic compressor. Hermetic compressors do not have crankcase ports. The only way to remove the oil is to remove the compressor, turn it upside down, and pour the oil out. It is also not possible to check the oil level on hermetic compressors because there is no oil sight glass. It is possible to add oil to a system with a hermetic compressor using a hand pump to force oil into the suction line. However, the technician cannot accurately measure the effect of adding the oil and has no reasonable way of removing the oil once it is in the system.

Semihermetic and Open Compressors

Adding or removing oil is more reasonable with semihermetic and open compressors. Small semihermetic compressors have a crankcase plug above the normal crankcase oil level that may be used for removing or adding oil (Figure 31-35).

Evacuating the Crankcase

Remember that the compressor crankcase is under pressure! The pressure must be removed from the compressor crankcase before removing any crankcase plugs. This may be accomplished by having the compressor pump itself down. Connect a set of gauge manifolds to the suction and

Figure 31-35 Crankcase plug in small, semihermetic air-cooled compressor.

discharge service valves on the compressor. Front-seat the suction service valve, energize the compressors, and operate the compressor until the crankcase pressure is below the mandated EPA recovery level for the refrigerant in the system. De-energize the compressor after it has pumped down, and front-seat the discharge service valve. Make sure the compressor cannot be turned back on.

The refrigerant will need to be recovered from systems that cannot or should not pump themselves down. Some compressor manufacturers do not want the compressor operating in a vacuum, even for a short period of time. Figure 31-36 shows the connections and valve positions necessary to recover refrigerant from the compressor. Make sure the compressor is off and cannot be turned on. Connect a set of gauge manifolds to the suction and discharge service valves on the compressor. Front-seat both the suction and discharge service valves, and recover the refrigerant to the EPA-specified level for the refrigerant in the system. Note that the under-200-lb rule may be used because the part that is isolated contains less than 200 lb.

Figure 31-36 Connections for recovering refrigerant from compressor.

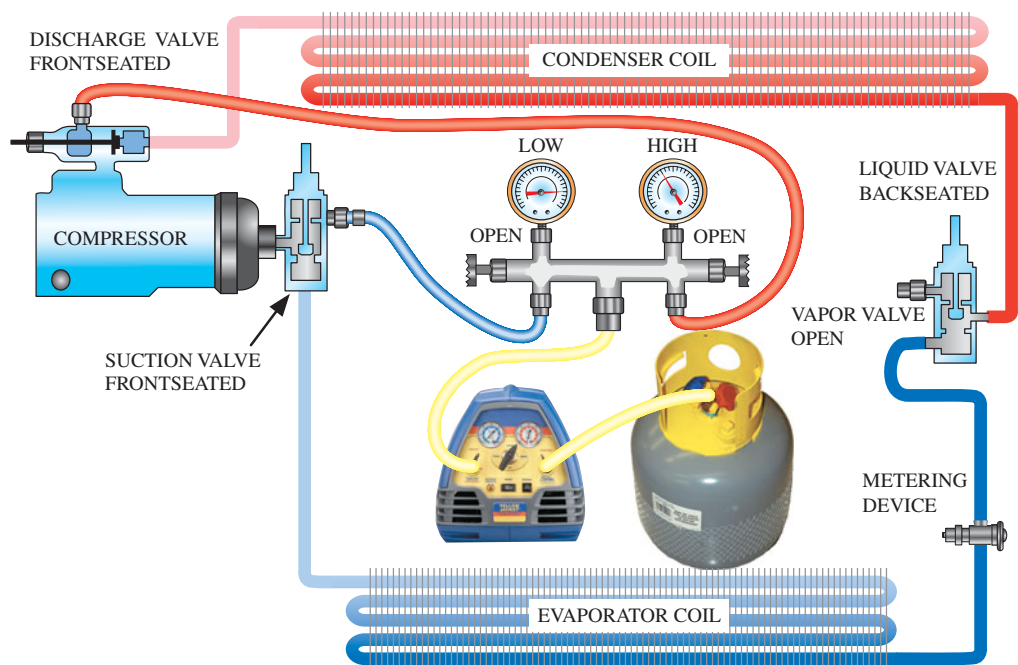

Figure 31-37 Crankcase drain plug on large compressor.

Removing Oil

An adapter can be used to remove oil from small semihermetic compressors. It provides a dip tube to the bottom of the crankcase. Once the adapter is in place, a few pounds of nitrogen introduced through the suction service valve will push the oil out the dip tube in the adapter.

Larger semihermetic and open compressors have crankcase drain plugs. Opening this plug allows oil to flow out of the compressor crankcase (Figure 31-37).

Adding Oil

The oil can be poured into the compressor crankcase after evacuating and opening the compressor crankcase. After the oil is added, the compressor will need to be evacuated. This should not take long, because only the compressor crankcase is being evacuated. After evacuating the compressor, the suction and discharge service valves are back-seated, allowing the system refrigerant back into the compressor.

Adding Oil Without Opening the Compressor Crankcase Using a Vacuum

In the evacuation method, the compressor creates a slight vacuum that is used to suck oil in. The oil line must

have a manual valve to control flow through the oil line. One end of the oil hose is connected to the suction service valve, and the other is submerged in the oil container. Purge the air from the oil line by blowing a small amount of refrigerant vapor through it into the oil. Front-seat the suction service valve and operate the compressor long enough to create a slight vacuum. Oil may now be added by opening the control valve in the oil line. Close the oil control valve when the oil level in the compressor crankcase sight glass is at the minimum fill level (see Figure 31-37). Back seat the suction service valve and remove the oil charging hose.

UNIT 31—SUMMARY

A system that has been evacuated is normally charged with liquid into the high side of the system with the system off. The amount of refrigerant added is measured by an electronic scale. The amount and type of refrigerant used in a system can be found by looking at the data plate. This amount must be adjusted for line length on split systems. Common forms of charging charts provided by manufacturers include charts that correlate operating conditions to system pressure, superheat, or subcooling. Superheat charts are used with fixed-restriction systems, while subcooling charts are used with thermostatic expansion valve (TEV) systems.

WORK ORDERS

Service Ticket 3101

Customer Complaint: System Not Cooling Properly

Equipment Type: R-22 Residential Split System

The technician arrives at the residence. The customer states that the system has not been cooling very well for the last few weeks. The technician asks to go in and look at the indoor unit and finds that the fan is running and that there is very little air coming out of the vents. The technician notes that there is a TEV on the evaporator and finds that the outdoor coil is clean and the condenser discharge air temperature is cool.

The technician suspects that the evaporator coil may be freezing. The technician asks to go back in the residence so that the evaporative coil can be defrosted. The technician turns the thermostat fan switch to ON and the system switch to OFF so that the fan will blow air across the coil to defrost it. During the defrost process, the technician watches the condensate drain to be sure that it does not overflow as a result of the large volume of water from the frozen coil.

Once the evaporator coil has been thawed, the technician returns to the outdoor unit to check the charge. The technician puts on his safety glasses and gloves and attaches the refrigerant manifold gauge set to the

system. The technician obtains the following pressures and temperatures:

- Suction-line pressure is 50 psi
- Suction-line temperature is 60°F
- Ambient air temperature is 85°F
- High-side pressure is 170 psi

The unit superheat chart calls for a superheat of 20°F, but the actual superheat is 32°F (50 psig = 28°F saturation 60°F – 28°F = 32°F). The technician determines that the system is low on refrigerant because the superheat is high. A leak is found on the Schrader valve. The technician uses a core-removing and -replacement tool to change out the Schrader core without having to remove the charge.

The charge is adjusted so that the proper superheat temperature is obtained. The technician notes the number of pounds of refrigerant that were added to the system. This information is put on the service ticket and recorded on the refrigerant log. The system is now operating satisfactorily.

Service Ticket 3102

Customer Complaint: System Is Tripping Main Circuit Breaker

Equipment Type: R-22 Residential Split System

The service technician checks to make sure the thermostat and compressor disconnect are turned off. Leaving the disconnect off, the technician checks and determines the compressor is grounded. The technician reports to the customer that the compressor is bad, and the customer wants the compressor replaced.

The technician checks the price book and provides the customer with a cost estimate for the job. The customer accepts the estimate, and the technician calls the office and has the parts department send a replacement compressor.

While the compressor is being delivered, the technician puts on safety glasses and gloves and proceeds to recover the refrigerant. After the refrigerant is recovered to the proper level, the technician replaces the compressor and installs the liquid- and suction-line driers. A leak test is then performed to verify a tight system.

With a leak-free system, the technician then evacuates and dehydrates the system to 500 microns. After determining the system is tight and dry, the refrigerant-charging process is started. To ensure the efficiency and longevity of the system, this process should be performed to the manufacturer's specifications.

The manufacturer's specifications dictate an approach-charging method. Using the manufacturer's supplied chart, the technician reaches the appropriate temperature difference between the outdoor ambient

temperature and the liquid-line temperature, thus completing the charging process.

After the technician cleans up all of the packaging and other scrap material from the worksite, the customer is provided with a service ticket.

Customer Complaint: Poor Cooling and High Operating Cost

Equipment Type: R-22 Split System, New Condensing Unit Replacement

A customer complains that her new air conditioner does not seem to cool as well as her old one and it costs more to operate despite the fact that the new system is a 14-SEER unit and the old one was a 10-SEER unit. The technician checks the system charge and finds that it is operating with a low suction pressure, a high superheat, and a high subcooling. The technician tries to adjust the charge, but it seems impossible. To get the superheat down to the recommended level, the high side has to be higher than the charging chart specifies for the ambient temperature. The technician decides to look at the indoor coil to look for clues and notices that the indoor coil is old. The technician uses a Web-capable cell phone to look for an AHRI match between the new condensing unit and the old coil and discovers the two pieces of equipment are not matched. The technician explains that SEER ratings apply to matched systems, not individual components. Since the condenser and evaporator are not an AHRI match, they will not work well together. The technician suggests that the customer have a coil installed that is an AHRI match to solve the problem.

Work to Be Performed: New System Startup

Equipment Type: R-410A Split-System Air Conditioner

A technician is called to perform a new system startup on an R-410A split system. The technician notices that the manufacturer lists the factory charge as adequate for 15 ft, but the lines on this system are 30 ft. The technician suspects that the system will need a small amount of charge to adjust for the extra line length but decides to check the system operation before adding refrigerant. The technician gets the following readings while checking the system charge: 130 psig suction pressure, 60°F suction-line temperature, 340 psig liquid pressure, 102°F liquid-line temperature. The technician's first impression is that everything looks good. However, the manufacturer calls for an 8°F subcooling, and the unit is operating with only 3°F of subcooling (340 = 105°F saturation). The technician throttles a small amount of liquid refrigerant into the low side with the system running, waits for 10 minutes, then rechecks the figures. The pressures

have not changed, but the liquid line is now 100°F, making the subcooling 5°F. The technician throttles in another small amount of liquid, waits, and rechecks the system. The pressures have remained stable, but the liquid-line temperature has dropped to 97°F, providing the correct subcooling.

UNIT 31—REVIEW QUESTIONS

1. Why are systems with fixed-restriction metering devices critical to charge?
2. How does an overcharge of refrigerant affect system efficiency?
3. Why must refrigerants that fractionate, such as R-410A, be charged as a liquid?
4. How does an undercharge affect the superheat of a fixed-restriction system?
5. How does an overcharge affect the superheat of a fixed-restriction system?
6. How does an undercharge affect the subcooling of a TEV system?
7. How does an overcharge affect the subcooling of a TEV system?
8. What is the best method for charging a large system that holds 50 lb of refrigerant?
9. What is the best method of charging a small appliance that holds less than a pound of refrigerant?
10. Using Figure 31-22, what would be the proper superheat for a system with an ambient temperature of 95°F and a return-air wet bulb of 70°F?
11. Using the information in question 10, you measure a suction pressure of 130 psig for an R-410A system. What should the suction line temperature be?
12. Using the information from questions 10 and 11, what charge adjustment should be made if the suction line measures 55°F?
13. Using Figure 31-28, what would be the proper subcooling for a system with an ambient temperature of 115°F and a return-air wet bulb of 62°F?
14. Using the information from question 13, what should the liquid-line temperature be if the liquid pressure is 293 psig for an R-22 system?
15. Using the information from questions 13 and 14, what charge adjustment needs to be made if the liquid line temperature is 110°F?
16. Why should a system be leak tested before it is charged?
17. Outline the procedure for adding oil to a semi-hermetic compressor without opening the compressor.
18. How often should the refrigeration oil in a compressor be changed?
19. Using Figure 31-30, what should the liquid-line temperature be for a model 10ACB30 unit operating in an ambient temperature of 97°F?
20. Using the information from question 19, what charge adjustment needs to be made if the liquid-line temperature is 110°F?
21. Using Figure 31-18, the suction pressure is 140 psig, the liquid pressure is 370 psig, and the ambient temperature is 105°F. What charge adjustment needs to be made?
22. Using Figure 31-18, the suction pressure is 155 psig, the liquid pressure is 360 psig, and the ambient temperature is 95°F. What charge adjustment needs to be made?
23. List the variables that affect system pressures.
24. Give an example of a condition that can make a system appear overcharged even though the charge is correct.
25. Give an example of a condition that can make a system appear undercharged even though the charge is correct.
26. What is the standard AHRI design condition used for rating unitary air-conditioning equipment?
27. Who is the most reliable source of information regarding the charge for any particular piece of equipment?
28. A new split-system air-conditioning system is being installed. The actual line length is 48 ft. The factory charge for the condensing unit is 94 oz. The installation instructions state that the factory charge assumes a line length of 20 ft and gives the per-foot adjustment as 0.6 oz/ft. How much refrigerant should be added to the system after the lines and coil have been evacuated?
29. The compressor in an existing split-system air-conditioning system is being replaced. The actual line length is 35 ft. The factory charge for the condensing unit is 100 oz. The installation instructions state that the factory charge assumes a line length of 15 ft and gives the per foot adjustment as 0.6 oz/ft. How much refrigerant should be added to the system after the system has been evacuated?

UNIT 32

Electrical Safety

OBJECTIVES

After completing this unit, you will be able to:

1. describe the harmful effects of electrical accidents.
2. recognize the significance of proper electrical safety procedures.
3. explain the function of ground fault circuit interrupters (GFCI).
4. determine if a circuit breaker has tripped and how to reset it.
5. lockout and tagout an electrical circuit.
6. test a circuit for voltage to make sure it is de-energized.
7. explain the safety importance of fuse and breaker amperage capacities.
8. describe why electrical wire types and sizes are important to safety.

32.1 INTRODUCTION

It is very likely that during your career you will work with electrical circuits and electrical equipment. You may be involved with new equipment installation and need to perform some finish wiring or retrofit wiring. You will also need to understand wiring and circuits for troubleshooting systems. This can be difficult because electrical theory and wiring are only one part of a HVACR technician's total body of knowledge. It may take years of service experience before you have a complete understanding of electrical systems and circuits. However, that does not mean that you cannot begin working safely beginning on the first day.

There is no excuse for poor safety practices. If the circuit is properly de-energized and locked out, then you will be safe. In the United States, electrical hazards cause more than three hundred deaths and four thousand injuries in the workplace every year. Electrical accidents rank sixth among all causes of work-related deaths. The Electrical Safety Foundation International (ESFI) recently reviewed data for a 5-year period and reported that a total of thirty-nine (15 percent) of the victims were electrocuted while servicing HVACR equipment. You need to understand how to protect yourself and the customer from electrical hazard. This unit will identify the steps that you need to take to ensure safe workplace practices.

CODE

OSHA's general industry electrical safety standards are published in Title 29 Code of Federal Regulations (CFR), part 1910.302–1910.308 (Design Safety Standards for Electrical Systems) and 1910.331–1910.335 (Electrical Safety-Related Work Practices Standards).

32.2 ELECTRICITY FLOW

Electricity needs a path to flow through. Substances such as metals offer very little resistance to electric current flow and are called conductors. This is why electrical wires are

normally made of metal such as copper, which not only conducts electricity but bends fairly easily without breaking. Insulation has the opposite effect. It resists the flow of electricity, and this is why electrical wires are not just bare but instead are enclosed by insulation that has a high resistance to electricity flow. A typical electrical cable with insulated wire is shown in Figure 32-1.

Wet and damp areas can often lead to electrical hazard even though pure water itself is a poor conductor. This is because any water or moisture present will not be pure

Figure 32-1 Three conductor NM electrical cable with ground.

but instead will most likely hold small amounts of impurities such as salts and minerals, which turn water into a very good conductor. As an example, dry wood is a poor conductor, but when saturated with water, it changes into a good conductor.

Similarly, your skin, when it is dry, also has some resistance to electricity flow. However, normally there will be some perspiration or moisture on your skin, which then turns it into an excellent conductor of electricity. The amount of current in amperes that passes through a body determines the severity of an electrical shock. One milliamp (one one-thousandth of an ampere) will provide a slight tingling sensation. Current flow of over 50 milliamperes will cause severe pain and at higher levels cardiac arrest.

The approximate body electrical resistance underneath the surface layer of your skin, from hand to hand across the body, is 1,000 ohms. Given this resistance, a current flow of 30 milliamperes would be generated with only 30 volts. Fortunately, the outside of your skin would provide for a higher resistance and therefore a lower current flow. However, if your skin was wet or cut, then the resistance would decrease and the current flow could increase to a potentially dangerous level even at this low voltage.

High-voltage systems (600 volts or more) provide a greater chance for fatal shock. However, it is easy to see that with only such a small amount of current flow required, electrical shock can be just as likely to happen when working on a low-voltage system if you come in contact with a conductor.

SAFETY TIP

The majority of electrocution deaths occur at low voltages. The false perception that low voltage is safe to work on may contribute to this statistic.

32.3 ELECTRICAL SHOCK

In an electrical circuit, the electricity will flow from the source through one wire (hot conductor) connected to the load and then back again to make a closed loop or closed circuit. If you touch a live wire, then you can become part of the circuit and the electricity can flow through you. Electricity can flow between parts of your body or through your entire body to the ground, as shown in Figure 32-2. This can lead to burns, electrical shock, and even death.

Figure 32-2 Coming into contact with an energized conductor will result in electric shock.

SAFETY TIP

Shocks occur when a person's body completes the current path with both wires of an electric circuit, such as one wire of an energized circuit and the ground; a metal part that accidentally becomes energized, such as a break in a wire's insulation; or another conductor carrying current.

A severe shock may cause internal damage and destruction of tissues, nerves, and muscles that may not at first be readily apparent. Also, electrical burns can occur as electricity flows through parts of the body. In the event of severe shock or electrical burns, immediate medical attention is required.

If a person is "frozen" and unable to pull free of the circuit, do not attempt to grab hold of him as then you will also become part of the live circuit. Instead, locate the power source and shut off the switch immediately. If this is not possible, try to use something nonconducting, such as a wooden broom handle, and try to safely push the person away from the contact.

To prevent the possibility of electric shock, the circuit should always be de-energized before it is worked on. Even when the circuit is de-energized, there still may be a residual electrical charge remaining in components such as capacitors. Always assume there is a voltage present when working with circuits having high capacitance, even when the circuit has been disconnected from its power source. Before working on de-energized circuits that have capacitors installed, they must be discharged using a safety shorting probe.

CODE

OSHA's electrical standards are based on the National Fire Protection Association (NFPA) Standards NFPA 70, National Electric Code, and NFPA 70E, Electrical Safety Requirements for Employee Workplaces.

32.4 BURNS

Burns are the most common type of shock-related injury. These can be classified as electrical burns, arc burns, thermal contact burns, or a combination of burns. The most serious are electrical burns. These occur when heat generated by the flow of current through body parts damages tissue. Since the burning is often mostly internal, there may be only a small wound on the surface. Even so, this should not be ignored. An electrical burn requires immediate medical attention.

A flash or explosion near a person's body due to an electric arc can cause severe burns. Protective clothing and gear will reduce the chance of exposure to the high temperatures that can be produced by an arc flash. An electric arc can be produced when there is a short circuit or poor electrical contact between conductors. It is important to note that physical contact with the conductor is not necessary. Even standing several feet away from the source of an arc may lead to severe or even fatal burns.

Bare skin that touches hot wires, hot motors, or other overheated electrical components will experience thermal contact burns. Thermal contact burns can also be the result of an electric arc explosion, as hot flying fragmented metal and splattering molten droplets will burn the skin and catch clothing on fire.

SAFETY TIP

You should always maintain a safe distance from a live circuit. On circuits of less than 300 volts, never contact a live conductor. On live circuits of 300 to 750 volts, you should never approach at a distance closer than 1 ft.

32.5 PROTECTIVE GEAR

Insulated rubber gloves should be used whenever testing live circuits. They should be marked with the appropriate voltage rating and last inspection date. Leather protectors worn over the gloves are used to reduce the chance that the rubber will be punctured. Never wear watches or rings while wearing insulated rubber gloves, and never wear anything conductive. Avoid wearing synthetic-fiber clothing. This type of clothing will burn rapidly and melt, which will increase the severity of the burn. Wear flame-resistant clothing instead.

Safety glasses or face shields should be worn whenever working on electrical circuits. You should always use insulated tools, and make sure that the insulation is not cracked or damaged. Use the proper type of plastic or fiber-glass-style fuse puller for installing or removing low-voltage cartridge-type fuses.

CODE

OSHA addresses the use of protective equipment apparel and tools in CFR 1910.335(a). This article is divided into two sections: Personal Protective Equipment and General Protective Equipment and Tools.

32.6 PORTABLE HAND TOOLS

A considerable number of electrical injuries occur from the improper use of portable, electrically operated hand tools. It is important to ensure that your tools are properly grounded. This means that the plug on the tool should have three prongs, as shown in Figure 32-3. For example, a faulty portable electric drill may have an uninsulated metal casing that would provide an electrical shock when turned on. A ground wire from the three-pronged plug will direct the stray current to ground rather than through the person holding the drill. The ground provides an easier path for the electricity to take rather than through your body, as shown in Figure 32-4. This increased flow of current to ground will normally activate the circuit-protection devices, which would shut off the power to the device.

Figure 32-3 Comparison of a three prong and two prong electrical plug.

CODE

If a conductor is connected to the earth or some conducting body that serves in place of the earth, such as a driven ground rod (electrode), the conductor is said to be grounded. Often in residential construction, the only grounding electrode that is available is the metal underground water piping system, as shown in Figure 32-5. The National Electric Code (NEC), section 250.53(D)(2), requires that whenever water piping is used as an electrode it must be supplemented, for example, with a ground rod. Also in NEC section 250.5 (A), the metal underground water pipe must be in direct contact with the earth for 10 ft or more, and the grounding clamp connection must be made within 5 ft of the point where the pipe enters the building. **Caution:** NEC Section 250.52 (B) requires that metal underground gas piping systems may not be used as a grounding electrode.

Figure 32-4 A grounded enclosure will protect a person from electric shock.

Figure 32-5 A ground wire may be connected to a cold water pipe if attached in accordance with the National Electric Code.

SAFETY TIP

Some portable electric tools provide for double-insulated casings and do not need to be grounded. This type of tool may only have a two-prong plug rather than three. If a tool plug has three prongs, never use an adapter to make it fit a two-prong receptacle unless the adapter is properly grounded. Some adapters, as shown in Figure 32-6, have a grounding connection, but this will not protect you unless it is attached to ground.

32.7 GROUND FAULT CIRCUIT INTERRUPTER (GFCI)

Always use a GFCI (ground fault circuit interrupter) receptacle to plug into if available. A standard GFCI receptacle is shown in Figure 32-7. A GFCI can interrupt the flow of

Figure 32-6 Electrical adapter for three-prong plug to two-prong receptacle with ground wire connection.

Figure 32-7 GFCI receptacle.

electricity in as little as 1/40 of a second to prevent electrocution. It compares the amount of current going into the electric device with the amount of current returning from it, and if the difference exceeds 5 milliamperes, the device automatically shuts down. Take, for example, the wire of an extension cord. If there were a break in the insulation exposing bare wire, and the extension cord was located in a damp or wet area, this could lead to electrical shock for someone using it. However, this type of fault would generate excessive current, and the GFCI receptacle would trip before any further damage was done. As further protection, the GFCI receptacle must be manually reset.

32.8 DETERMINING DE-ENERGIZED CIRCUITS

An energized circuit is normally referred to as being "closed." This would be considered to be a "live" circuit. A de-energized circuit is "open." Think of a typical appliance plug. When it is plugged in to the receptacle, it is energized (closed), and there is power to the device. When it is unplugged from the receptacle, it is de-energized (open), and the device shuts down.

32.9 BREAKERS AND SWITCHES

In electrical circuits, switches and breakers are used to energize and de-energize the circuit. Think of a light switch. The lights are on, the switch is closed, and the circuit is energized. The lights are off, the switch is open, and the circuit is de-energized. Therefore, one way to check a circuit is to check its switch or breaker to determine whether the circuit is energized. In some cases, there may be more than one switch or breaker for the device. Take, for example, a residential service panel, as shown in Figure 32-8. There is a main disconnect switch that will shut off power to the entire building. Then there are separate circuit breakers that supply separate house circuits. Which switches and breakers are to be opened (turned off) will depend on the type of service work to be performed.

Figure 32-8 Service entrance panel.

SAFETY TIP

There is still power being supplied to a residential service panel even with the main disconnect switch is open (off). This is the power coming from the outside utility pole to the panel. The supply wires of the service entrance cable will still be “live.”

32.10 CIRCUIT BREAKERS

Circuit breakers typically have three positions. The two most common positions are when the breaker is on or off. The third position is when the breaker is tripped due to an overcurrent situation. If the breaker is tripped, as shown in Figure 32-9, it is positioned in the middle and is not in the off or on position, so it will need to be reset. Even though the breaker is not in the off position, it is tripped and no power is being supplied to the circuit. The reason for this middle position is to allow you to easily look through all the breakers in a service panel to see if there is a fault somewhere.

Generally, to reset a breaker you will need to push it into the off position, and you should hear a slight click and then push it back into the on position and you will

again hear it click as it snaps closed. Generally with breakers there is a “snap” action. Some motive force, such as a spring, will close the contacts. In breakers, the contacts are normally enclosed so they are not visible unless you break them apart.

Circuit breakers can be easily replaced. They simply connect to the bus bar with a clip located on the back side of the breaker, as shown in Figure 32-10. Never replace a circuit breaker until you have tested the circuit to ensure that the power is secured and there is no voltage present. It is not enough to just shut the power off. Always test the circuit for voltage as a double-check that the breaker is safe to remove.

SAFETY TIP

Never reset a circuit breaker until the cause of the fault is determined. The circuit breaker tripped due to a surge of current through the circuit. If you try to reset the breaker and the fault has not been corrected, it will trip again. An overcurrent condition can lead to equipment damage and even fire. Determine why the breaker tripped and correct the condition before resetting the breaker.

Figure 32-9 15-amp circuit breaker.

Figure 32-10 Removing a circuit breaker.

TECH TIP

Electric motors withstand hours and hours of running time and quite a bit of abuse. If a circuit breaker has tripped, it could be due to a shorted electric motor. A motor that runs hot for a prolonged period may experience insulation breakdown. This can lead to a short, where the electricity bypasses its normal path of flow. It is a “shortcut” for the electricity, and this allows for more electricity to flow (current increases). The wires in the circuit will not be large enough to carry this extra current, and they can overheat, melt, and cause a fire. Before this happens, the circuit breaker will trip.

32.11 GFCI BREAKERS

GFCI breakers are often used for equipment to be located outdoors in damp or wet locations. The GFCI breaker, as shown in Figure 32-11, has three positions: on, off, and tripped. It is reset like any other circuit breaker. You will need to push it into the off position, and you should hear

30 AMPERE 240 VOLT GROUND FAULT INTERRUPT BREAKER

Figure 32-11 GFCI circuit breaker.

Figure 32-12 Tripped GFCI circuit breaker.

a slight click and then push it back into the on position and you will again hear it click as it snaps closed. The GFCI breaker also has a test button. When this button is pushed, the breaker will trip and then must be manually reset. This type of breaker can be periodically tested in this way to make sure that it is functioning properly. A GFCI breaker wired in a circuit is shown in Figure 32-12. From the position of the switch, you can see that the breaker is tripped. GFCI circuit breakers can also be replaced similarly to standard-type circuit breakers, as shown in Figure 32-13.

32.12 SWITCHES

General-duty switches are designed for use in residential and commercial applications. These are used for relatively light-load applications such as general air conditioning and appliance loads. There are several different kinds of these switches, and some will have fuses while some others will not. A typical residential safety switch is shown in Figure 32-14. Unlike breakers that have a “snap” action, switches may consist of a throw handle that engages blades and clips, sometimes called a knife switch, as shown in Figure 32-15.

Figure 32-13 Removing a GFCI circuit breaker.

Figure 32-14 Safety switch enclosure. SAFETY SWITCH WITH COVER CLOSED

COVER OPEN

**Figure 32-15** Manual switch with blades and clips.

On lower-voltage systems, the person throwing the switch manually engages the blades and clips together to energize the circuit. Slow operation of the switch can cause the blades and clips to arc.

Heavy-duty motor-rated switches are commonly found on motor control boxes and feeder boxes for refrigerant controls in larger commercial systems, as shown in Figure 32-16. These will typically have three blades and clips for three-phase AC power, as shown in Figure 32-17. Since arcing is more pronounced on these types of larger switches, a quick-break operation prevents an operator from closing or opening the switch too slowly. This is similar to the “snap” action of a circuit breaker. For safety, when the switch is closed (energized), an interlock switch prevents the door from being opened, as shown in Figure 32-18. The handle must be turned off (de-energized)

before the door can be opened. When the door is open, the interlock prevents the handle from being turned on (energized).

32.13 LOCKOUT/TAGOUT

When working in a residential setting, the first step before beginning any electrical work is to turn off the power to the circuit at the service entrance panel. Any other safety switches between the service panel and the component to be serviced should also be shut off. You want to be 100 percent positive that the customer or anyone else working in the area will not turn the power back on to the circuit while you are working on it. **Never assume that they know you are working on the circuit!**

The customer should be informed that you are working on the circuit and the breaker should be physically locked out, as shown in Figure 32-19. You should attach a tag that includes your name, your company, why you have the breaker locked out, and the date. In the event that you do not finish the work and do not return to the residence, this provides information on who shut the power off and when it was secured. It is always preferable to physically lock out the circuit. Disconnect switches normally have a built in method for locking them, as shown in Figure 32-20.

SAFETY TIP

Always check the component for voltage even after you have shut the power off the circuit. If you temporarily leave the area, always retest the circuit before continuing to work on the component.

An apartment or condominium may have a maintenance supervisor overseeing the complex. On this type of job site, there is a greater potential that someone could accidentally turn the power on while you are working on the circuit. In this type of setting, it is always preferable to physically lock out the circuit you are working on. The maintenance supervisor should be informed that you are working on the circuit. Never assume that the circuit is safe. Always test the circuit before working on it.

CODE

OSHA’s lockout/tagout standards are published in Title 29, Code of Federal Regulations (CFR), part 1910.147, The Control of Hazardous Energy (lockout/tagout), and 1910.147 App A, Typical Minimal Lockout Procedures (when only tagging is possible).

In an industrial setting, there are often lockout/tagout procedures for the facility as shown in Figure 32-21. OSHA

Figure 32-21 Lockout/tagout instructions.

Figure 32-22 Locks and job journal record book.

Figure 32-23 Industrial electrical switchboard.

has regulations regarding lockout and tagout of equipment while it is being serviced. It is important that you follow these and all other electrical safety practices. You must receive proper authorization before locking and tagging out breakers or removing the lockout/tagout. You must understand and follow the procedures and record the action taken in a job journal, as shown in Figure 32-22. An industrial switchboard is shown in Figure 32-23. A safety placard is attached to the switchboard, as shown in Figure 32-24. The proper way to lockout and tagout a breaker is shown in Figure 32-25.

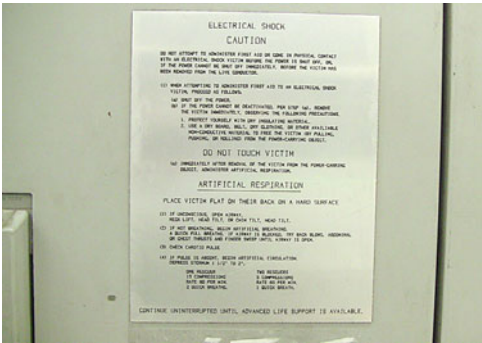

Figure 32-24 Electrical safety placard posted on switchboard.

Figure 32-25 Breaker properly locked and tagged.

SAFETY TIP

As a safety precaution, the only person who may remove a lock or tag is the person who placed it there. In some instances there may be multiple locks and multiple tags on one circuit breaker. The circuit cannot be energized until all tags and locks are removed by the individuals who placed them there.

32.14 MULTIMETERS

A volt-ohm-meter (VOM), also known as a multimeter, is often used to test a circuit to determine if it is energized. You should be thoroughly familiar with the meter you are using. A category III multimeter is shown in Figure 32-26. Multimeters are explained in further detail in Unit 35, Electrical Measuring and Test Instruments. You should always use the properly rated meter for the circuit you are testing. There are four category ratings for multimeters: CAT I, CAT II, CAT III, and CAT IV. Protected electronic equipment can be tested with a CAT I meter. Appliances, portable tools, and single-phase receptacles can be tested with a CAT II meter. Commercial lighting and equipment would require a CAT III meter. An outside service connection, such as from the utility pole to the power meter, would require a CAT IV meter.

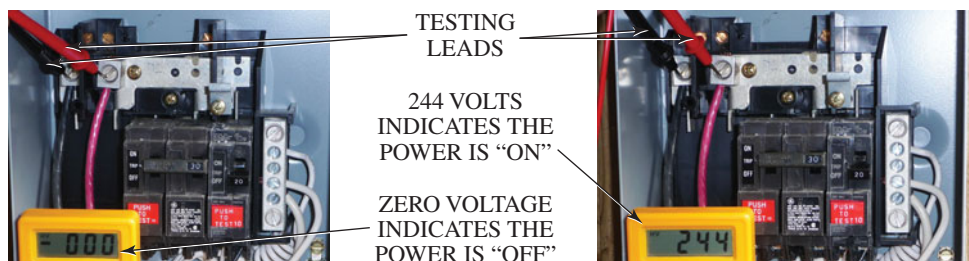

SAFETY TIP

Never use a meter that is rated for a lower category. As an example, a CAT I meter would not provide the proper protection for use on commercial equipment. Also look for a symbol and listing of an independent testing lab, such as UL, CSA, TUV, or other recognized testing organization, to ensure that the meter meets the required standards. The meter test leads should also be certified to a category and voltage as high or higher than the meter.

Figure 32-26 Category III multimeter.

Figure 32-27 Testing the voltage of a circuit with a multimeter.

32.15 TESTING THE CIRCUIT FOR VOLTAGE WITH A MULTIMETER

Always try to work on de-energized circuits whenever possible, and follow the proper lockout/tagout procedures. Wear protective gear and stand on an insulated mat. Test the circuit in the following manner.

1. Make sure the circuit is off and properly locked out and tagged out.
2. Test the meter on a known voltage source.
3. Test the circuit that should be de-energized (off).
4. Test the meter again on a known source to ensure that you didn't damage your meter or blow a fuse and get a "0" volt reading accidentally in step 3.

Try to rest or hang the meter whenever possible rather than holding it in your hands. Connect the ground test lead first and then the hot test lead. Reverse this procedure to do the opposite for removal. Remove the hot test lead first and then the ground test lead. Try to keep one hand in your pocket to lessen the chance of a closed circuit across your chest and through your heart.

To test for voltage, the meter must be set appropriately to read direct current (dc) or alternating current (ac), and also the proper scale must be used. Typical residential service is 120V and 240V. Digital meters are very precise, so the reading may show something slightly higher or lower than the expected reading. When testing a circuit to determine if it is de-energized, a reading of 0 V is required, as shown in Figure 32-27.

32.16 NONCONTACT VOLTAGE TESTERS

Noncontact voltage testers do not require physical contact with the live, current-carrying conductors. This type of voltage tester works by detecting the electromagnetic field that surrounds a "live" conductor. When the noncontact voltage tester is waved close to a conductor, it will provide an audible beep and a light will flash, as shown in Figure 32-28.

When using this type of voltage tester, you must still follow the same four steps outlined for testing a circuit with a multimeter to ensure that the noncontact voltage tester is working properly. Only use a detector that is rated for the level of voltage being measured and is sensitive enough for your application.

Figure 32-28 Testing the voltage of a circuit with a noncontact voltage tester.

THERE MAY BE A VISUAL INDICATION IN THE CENTER OF THE FUSE TO INDICATE IF IT IS BLOWN

Figure 32-29 Visual indication for the condition of a plug-type fuse.

32.17 FUSES

Circuit breakers are typically designed to trip the circuit and can be reset when the fault condition is corrected. Fuses are often one-time blowout devices that de-energize the circuit in the event of an overcurrent situation. When a fuse is blown, it must be replaced. Plug-type fuses generally have an indicator that will allow you to visually determine if the fuse is blown, as shown in Figure 32-29. If the fuse is of the cartridge type, often the only way to determine its condition may be to test the circuit with a multimeter. However, some cartridge-type fuses have a visual indicator, as shown in Figure 32-30. To replace the fuse, always de-energize the circuit first. Always use a plastic or fiberglass-style fuse puller for removing and installing low-voltage cartridge fuses, as shown in Figure 32-31.

SAFETY TIP

Always de-energize the circuit before replacing fuses. If the circuit is live, then the fuse will act like a knife switch when you try to install it. The blown fuse stopped the flow of current, so as it is removed it will not arc. The new fuse will allow current to flow as soon as it engages into the fuse clips. Since the fuse must be placed firmly into the clips, it will arc severely as soon as it comes into contact with the clips if the circuit is left energized.

Figure 32-31 Removing a cartridge-type fuse with a fuse puller.

32.18 CIRCUIT BREAKER AND FUSE SIZES

The current carrying capacity of a fuse or circuit breaker is an essential safety factor. These devices are designed to open and de-energize the circuit in the event of an overcurrent situation. If too much current flows through the circuit, the wires can become hot and overheat. This can lead to a fire. Excessive current will also cause damage to equipment that can become very expensive. If the breaker is sized too large, then it will not provide for the safety of the circuit. For example, a breaker that is rated at 30 amps installed into a 15-amp circuit would allow for too much current to flow.

It is also incorrect to install too small a fuse or breaker into a circuit, because this will lead to nuisance trips. For example, a breaker rated at 15 amps is installed into a 30-amp circuit. The system might operate normally for a period of time, but as additional components, fans, lights, etc. that are

Figure 32-32 Identification of markings found on electrical cable.

part of the circuit begin to turn on, the current will continue to climb. The breaker will trip. If the improper-size breaker was not identified, then this can be difficult to troubleshoot, because there was no actual fault. The circuit was working correctly but the breaker was not sized properly to handle the current flow.

32.19 ELECTRICAL WIRE SIZES AND TYPES

One of the most important considerations in an electrical circuit is the wiring size and type of wiring. National and local electrical codes require specific wiring types and sizes depending on the application. Electrical cable contains two or more insulated wires and may contain a grounding wire. It is classified according to where it will be used for dry, damp, or wet locations and exposure to sunlight and rough use, as shown in Figure 32-32. Nonmetallic sheathed cable (Type NM) is widely used for branch circuits and feeders in residential and commercial systems. NM cable is flame retardant and moisture resistant but suitable for dry locations only. Underground feeder cable (Type UF) is sunlight and moisture resistant, suitable for outside use, and can be buried under the ground. Another common type of cable is THHN, which is an abbreviation that stands for “thermoplastic high heat-resistant nylon-coated” and is suitable for dry and damp locations.

Wire sizing is expressed in American wire gauge (AWG) numbers, ranging from 50 to 0000. The smaller the number (gauge), the larger the diameter the wire will be, as shown in Figure 32-33. Wires larger than 1 gauge are designated as 0, 00, 000, and 0000 (one aught [1/0], two aught [2/0] etc.). A sample of different wire sizes and types is shown in Figure 32-34. While in some cases 14-gauge wire may be suitable for residential lighting circuits, 12-gauge wire is often recommended for residential receptacle outlets. The 12-gauge wire is thicker and harder to work with, but using a wire that is too small in diameter can lead to overheating and potentially fire. Receptacles will draw more current than lights; therefore it is often advisable to use the larger-diameter 12-gauge wire even if it is more difficult to work with. Always refer to the requirements of the local building codes for the location where you are working. Also realize that local codes change from time to time, so you must keep up with the current regulations on a regular basis.

UNIT 32—SUMMARY

Electrical work should be performed on systems that are de-energized with all power turned off. It is extremely important that you follow all safety rules and recommendations when working on electrical systems. Circuits should be tagged and

locked out before any electrical work is performed. Even after the power is secured, the circuit should be tested for voltage to ensure that it is safe to work on. OSHA has regulations regarding lockout and tagout of equipment while it is being serviced. It is important that you follow these and all other electrical safety practices. Electricity does not provide you with one free mistake. Your first mistake or careless act can result in serious injury or death.

Basic Electricity

OBJECTIVES

After completing this unit, you will be able to:

1. explain how the structure of the atom affects electricity.
2. discuss the difference between a conductor and an insulator.
3. explain the difference between direct current and alternating current.
4. list the characteristics of electric current that are commonly measured and the units used to measure them.
5. explain the relationship of potential, current, and resistance in an electrical circuit.
6. discuss the three elements required to make an electrical circuit.
7. explain the difference between series, parallel, and series parallel circuits.
8. use Ohm's law and/or the power formula to calculate values for volts, amps, ohms, and watts.

33.1 INTRODUCTION

Electricity and electrical problems are the most common issues HVACR technicians encounter. Installation and service both require an understanding of the basic electrical characteristics. A fundamental knowledge of electricity is required to truly understand all the electrical components in an air-conditioning system. Understanding electrical circuit characteristics and how to measure them allows technicians to test and analyze circuits in air-conditioning systems. Therefore, it is essential that technicians have a good understanding of basic electrical theory.

33.2 STRUCTURE OF THE ATOM

It is necessary to understand the structure of the atom to understand electricity. The smallest piece of an element that can exist and still retain the same chemical properties is the atom. Atoms are made of small particles called protons, neutrons, and electrons. Protons are positively charged, electrons are negatively charged, and neutrons have no charge. In the center of the atom is a nucleus composed of protons and neutrons. Clouds of negatively charged electrons are arranged in energy levels around this nucleus (Figure 33-1). Usually, the number of electrons and protons are equal, so the atom is neither negatively charged nor positively charged. The negatively charged electrons are held in the atom by their attraction to the positively charged nucleus. The electrons are arranged in energy levels, with fewer electrons in the energy level closest to the nucleus and more electrons in the energy level farthest away from the nucleus. Each energy level has a maximum number of electrons that it will hold. The maximum number of electrons in each energy level is two in the first, eight in the second, eighteen in the third, and thirty-two in the fourth. As atoms become larger with more electrons, some electrons end up farther away from the nucleus. The electrons that are farther away from the nucleus are not as tightly

Figure 33-1 A simple carbon atom has a nucleus of positively charged protons surrounded by negatively charged electrons.
(Courtesy of NOAA)

bound to the atom because the attraction is weaker. When just a few electrons are in an outer orbit, they can escape the bonds of their atom. Electrons that have escaped their atomic bonds are called free electrons. Figure 33-2 shows a copper atom. The first three energy levels are filled, leaving one electron in the outermost energy level.

33.3 FLOW OF ELECTRONS

Electricity is the flow of electrons. Electrical flow is not like pouring electrons in one end of a wire and dumping them out the other. Rather, electricity is more like a string of dominoes. One bumps the next and the energy flows from one end to the other, but no individual domino moves very far. With electricity, an electron moves from one atom to another and causes an electron to leave that atom. This electron then moves to a neighboring atom, which causes it to lose an electron. This chain reaction carries through the wire to provide an electrical current (Figure 33-3). Energy is required to start and maintain this chain reaction and get all the free electrons moving in the same direction.

Figure 33-2 The first three electron energy levels of a copper atom are full, but the outer level has only one electron.

33.4 CONDUCTORS AND INSULATORS

Electrons can flow through some materials more easily than other materials. Atoms that have just a few electrons on their outer energy level make good conductors because those electrons can more easily become free electrons (see Figure 33-2). Materials with a large number of free electrons make good electrical conductors. Most metals are good conductors because they have a large number of free electrons that are not bound to any particular atom. Gold, silver, copper, and aluminum are all excellent electrical conductors. This list is arranged in order of the metal's ability to conduct electricity, with gold being the best conductor. Gold and silver are both commonly used as electrical conductors in electronic circuits where the amount of material is small (Figure 33-4). Copper is used most often in wiring because of its lower cost compared to gold and silver and its superiority to aluminum in conductance (Figure 33-5).

Insulators have far fewer free electrons, so they resist the flow of electrons. The outer energy level of an insulator is typically full, making it more difficult for electrons to escape. Ceramic, rubber, and plastic are examples of insulators. Thermoplastics are commonly used for the insulator on wires because a very thin layer of thermoplastic can resist

hundreds of volts. A thicker insulation layer is required to contain higher voltages. The voltage feeding sparkplugs in car engines is several thousand volts. Sparkplug wires have a much thicker insulation jacket than house wiring because they need to contain higher voltages. Figure 33-6 shows a comparison of the insulation on a power wire and on a sparkplug wire. Ceramic insulators are used in high-voltage applications that also require physical strength. The insulators on high-voltage power-distribution lines are ceramic.

33.5 SEMICONDUCTORS

The revolution in electronic circuits is based on the discovery and advancement of semiconductors. Semiconductors can behave like a conductor or like an insulator. This behavior allows them to be used like an electronically controlled switch. Silicon, carbon, and germanium can form uniform crystals because they have four electrons in their outer shell. Silicon is the most commonly used semiconductor material. The addition of trace amounts of another chemical into the crystalline structure is called doping. Doping alters the semiconductor's electrical properties. Doping can produce either a positive or negative charge in the semiconductor material, depending on the chemical used. N-type (negative) semiconductors are doped with phosphorus and arsenic; P-type (positive) semiconductors are doped with boron and gallium. The N-type and P-type materials are joined together to make semiconductor devices like diodes, transistors, and rectifiers.

33.6 STATIC ELECTRICITY

Static electricity is a very common phenomenon that we all have experienced at one time or another. You may have walked across the rug and then reached for the doorknob and unexpectedly felt a static shock. The reason for this can be simply explained.

Static versus Dynamic

Electricity can be classified as either static or dynamic. Something that is static is stationary; something that is dynamic is in motion. Static electricity is the result of a standing charge, while dynamic electricity is in motion. Dynamic electricity has a current created by flowing electrons.

Static Charges

Objects can be neutral, positively charged, or negatively charged. If the number of electrons and protons in an object

Figure 33-3 Electron flow occurs as a chain reaction.

Figure 33-4 The contacts on the edge connector of this circuit board are made of gold.

Figure 33-5 This wire is made of copper.

Figure 33-6 The insulation on the wire on the left is designed for up to 600 V; the insulation on the wire on the right is designed for thousands of volts.

Figure 33-7 Lightning is a powerful example of static electricity. (Courtesy of NOAA Photo Library, NOAA Central Library; OAR/ERL/National Severe Storms Library [NSSL])

are equal, it will be neutral and will not have an electrical charge. If an object picks up additional electrons, it will become negatively charged because electrons have a negative charge. If an object loses electrons, it will become positively charged. Static electrical charges are the result of friction, where electrons are literally rubbed off from one object to another, creating one positive and one negative charge.

Examples of Static Electricity

If the difference in charge between the two objects is great enough, electrons will jump from the negatively charged object to the positively charged object. Lightning is probably the most common type of static electricity (Figure 33-7). Lightning occurs during a storm when cloud particles acquire large amounts of electric charge as they rub across the ground. Meanwhile, the ground has built up an opposite electric charge. A lightning bolt is created when the difference in charge becomes strong enough and the clouds get close enough to the ground for the electrons to jump. A smaller charge is acquired in dry weather by a person walking along a thick rug, collecting negative charges from the rug as a result of friction. A spark jumps from the person to an object when the person reaches to touch it, because of the static charge he or she has built up.

SERVICE TIP

There are many printed circuit boards currently being used in the HVACR field containing electronic chips that control the functions of the system. These electronic chips can be damaged by an accidental discharge of static electricity. Always discharge yourself by touching the equipment frame when working around equipment with electronic components.

Static electricity has few practical uses, but one rather common device called an electrostatic precipitator uses static electricity to filter the air. Air is passed through a plastic medium that is charged by static electricity from the

movement of the air. The static charge is used to attract and trap the particles in the airstream. The process is very effective in removing fine dust particles and pollen from the air.

33.7 PRODUCING DYNAMIC ELECTRICITY

Other forms of energy that can be used to generate electricity include heat, light, chemical, mechanical, and magnetic. They generate electricity by moving free electrons. The two most common forms of energy used to generate electricity are chemical energy and magnetic energy.

Batteries

Batteries generate electricity by turning chemical energy into electrical energy. Two chemical reactions take place in a battery: one gives off free electrons, and the other absorbs free electrons. A car battery is an example of a typical wet-cell battery. Lead and lead oxide are immersed in acid. The negative terminal is connected to the lead because the reaction between the lead and the acid creates free electrons. The positive terminal is connected to the lead oxide because the reaction between it and the acid absorbs free electrons (Figure 33-8). Electrons will flow from the negative terminal to the positive terminal when a path is created between them.

SAFETY TIP

Never create a path from one battery terminal to the other using only a conductor. The large current flow created has enough energy to melt the wire or cause the battery to explode! Any path between the two battery terminals should contain a load, such as a lightbulb, fan motor, or some other device. A load has the ability to resist current flow and turn the electrical energy into useful work.

Generators

Generators use magnetic and mechanical energy to create electricity. When a magnetic field is placed near a conductor, the free electrons in the conductor line up with the

Figure 33-8 In a lead-acid battery, the reaction between the lead and sulfuric acid produces a negative charge while the reaction between the lead oxide and the sulfuric acid produces a positive charge.

Figure 33-9 Free electrons in a conductor are pulled by the magnetic field moving past the conductor.

magnetic field. Moving the magnetic field pulls the free electrons with it, creating electron movement and current flow in the conductor (Figure 33-9). Generators use this principle to transform magnetic and mechanical energy into electrical energy.

33.8 CURRENT, VOLTAGE, WATTAGE, AND RESISTANCE

Electrical circuit operating characteristics can be measured. The common measurement terms used are *current*, *voltage*, *wattage*, and *resistance*. Current refers to the flow of electrons, voltage is a measurement of potential, wattage indicates power, and the opposition to the flow of electricity is called resistance.

Electric Current: Amps

The coulomb is the measure of electrical charge. One coulomb is equal to the charge of 6.241506×10^{18} electrons. Coulombs are seldom used in practical measurement. Instead, the rate of electrical current flow is measured when testing electrical equipment. The rate of electrical current flow is measured in amperes, abbreviated "amps." Electrical current is flowing at the rate of 1 amp when 1 coulomb of electrons passes by in 1 second. Amperes are represented in equations and formulas by the letter *I*, for "intensity," because amperes are a measure of the intensity of the electric current.

Electric Potential: Volts

The ability to make current flow is called electromotive force or potential. Potential difference provides the electrical pressure that makes current flow possible. Current flows through a conductor because of a difference in potential from one end of the conductor to the other. Voltage is a measure of the potential difference. Without a difference in voltage from one end of the wire to the other, there will be no current flow. Voltage is represented in equations and formulas by the letter *E*, for "electromotive force."

Electric Work: Watts

The ability of electricity to do work depends on two factors: voltage and current. The watt is a measure of the rate at which electrical work is done. Wattage depends upon both voltage and current. A watt is defined as 1 ampere of current flowing at a potential difference of 1 V. Wattage can be calculated using the formula $\text{volts} \times \text{amps} = \text{watts}$. Wattage is not truly a quantity but a rate. Wattage does not measure the amount of work accomplished; it measures the rate at which work is accomplished. Wattage is a rate because it is

calculated using amps, a measure of electrical current flow. Remember that flows are always measured as a rate. Watts are sometimes represented in equations and formulas by the letter P , for “power,” and sometimes by the letter W , for “watt.”

Wattage is a reasonable measure for small appliances and light bulbs, but if you are heating a house you need something that works better for large measurement. Kilowatts, abbreviated kW, are used to specify the energy use of heating and air-conditioning equipment. A kilowatt is equal to 1,000 W. The formula is simply watts/1,000 = kilowatts. Kilowatts are represented in equations and formulas as kW, for “kilowatt.”

Watts and kilowatts are really both rates, not quantities. Electrical quantity is measured in kilowatt hours. Power companies use kilowatt hours to measure the amount of electrical work you did during the month. This is calculated by measuring kilowatt use over time. Kilowatt hours are represented in equations and formulas as kWh, for “kilowatt hours.”

Resistance: Ohms

To some extent, all conductors and electrical devices resist current flow. The ratio of voltage to current is the resistance, and it is stated in ohms. Ohms are represented in formulas and equations as R , for “resistance,” or the Greek letter omega, Ω , for “ohms.” The resistance of a conductor is affected by the physical properties of the material, the cross-sectional area of the conductor, and the length of the conductor. Smaller-diameter wires have a higher resistance than larger-diameter wires. Long conductors have a higher resistance than shorter conductors.

TECH TIP

The resistance of most conductors increases as they rise in temperature. The low ohm reading of a cold lightbulb increases almost instantly as it heats up and begins to glow, giving off light. This change in resistance occurs with any conductor as it is heated. Hot conductors have higher resistance than cold conductors.

33.9 DIRECT CURRENT

Direct current, DC , is a continuous flow of electrons in one direction (Figure 33-10). All batteries supply DC current. In the HVACR trade, DC current is used primarily for operating cordless tools. Direct current is also used in special applications, such as the control systems in transportation refrigeration equipment, the cells in electronic air cleaners, and operating electronic circuits.

33.10 ALTERNATING CURRENT

Unlike DC current, which flows continuously in one direction, alternating current alternates its direction of flow through the conductor. It flows in one direction and then

Figure 33-10 Electrons flow in only one direction with direct current.

the other at regular intervals (Figure 33-11). The AC waveform is shaped like a sine wave. Half the time the current is positive and half the time it is negative. The period of time required for the voltage to peak in both directions and return to 0 V is called a cycle. Figure 33-12 shows one cycle of alternating current.

Frequency

The frequency of AC current is the number of cycles per second. Frequency is measured in hertz (Hz): 1 Hz is equivalent to one cycle per second. In the United States, 60 Hz power is standard. In Canada and many other parts of the world, the standard is 50 Hz.

Phase

The number of these waveforms occurring at the same time is called the phase. AC is available in single phase and three phase. A single-phase AC circuit requires only two wires. A three-phase circuit requires three wires: one for each phase. Three-phase power is advantageous for operating electric motors and for transferring large amounts of current. Residences use single-phase AC power, while commercial and industrial buildings typically are supplied with three-phase power.

Figure 33-11 In alternating current, the direction of electron flow reverses at regular intervals.

Figure 33-12 One complete cycle of alternating current.

Voltage

The voltage used in an AC circuit changes constantly. The average voltage supplied is 0 because the two halves of the sine wave cancel each other out. Therefore, AC voltages are stated in effective voltage. The DC voltage that would produce the same heating effect in an electric heater is established as the effective AC voltage.

The effective voltage of a pure sine wave is 0.707 times peak voltage. For example, an AC current with a peak voltage of 170 V is rated at 120 V because it produces the same amount of heat in an electric heater as a DC voltage of 120 volts. This is shown mathematically as: $170 \text{ peak volts} \times 0.707 = 120 \text{ effective volts}$ (Figure 33-13).

TECH TIP

A mathematical formula called the “root mean square” is used to calculate the effective voltage. The instantaneous voltage is measured many times each cycle. Each of these values is squared, the average of the squares is found, and finally the square root of the average is the effective voltage. This can be reduced to a simple factor of 0.707 for AC currents that are pure sine waves. The 0.707 factor is not accurate for other waveforms.

**Figure 33-13** The effective voltage is 0.707 times the peak voltage.

33.11 COMPARISON OF AC AND DC POWER

AC power is produced by electrical power-generating plants because it is efficient to generate and can be transmitted over long distances. DC power is commonly found in many low-voltage applications, especially where these are powered by batteries. This is because batteries that are used in many portable electrically operated devices produce only DC power.

Reason for AC Current

Transmission of large amounts of power involves unavoidable line losses due to the resistance of the wires. The power lost in the line is calculated using the formula I^2R . Keeping the current, I , low is the key to reducing line loss. By utilizing high voltages, the power can be transmitted by using relatively low line current, thus minimizing the line losses. The voltage level of AC current can be more easily changed, or transformed, than DC current. This allows AC current to be transformed to extremely high voltages for transmission across long distances and then transformed at the point of use back down to a safe voltage level.

DC Electrical Power Generators

Electrical power generators have a shaft called a rotor that spins in a stationary housing called the stator. DC generators are designed differently than AC generators. A magnetic field induces current to flow in the armature windings located in the rotor for DC generators as compared to the armature windings located in the stator for AC generators. In a DC generator, the magnetic north and south poles are placed in the housing (stator), and the windings located in the rotor generate current as it spins through the magnetic field (Figure 33-14). Drawing this current flow from the rotor, which is spinning very fast, involves a complex arrangement of a commutator and brushes. As the total amount of current and voltage required increases, it becomes more difficult and less practical to draw the current from the spinning rotor.

AC Electrical Power Generators

AC generators spin the north and south poles with the rotor (Figure 33-15). The armature windings are located in the

Figure 33-14 Operation of a DC generator.

Figure 33-15 Operation of an AC generator.

stator, and the power is tapped directly from them to make for a much simpler arrangement. The distribution wires are larger and the power drawn will be greater as compared to a DC generator. Therefore AC generators can be designed to more easily produce the large amounts of power required of large electrical power plants.

TECH TIP

In an AC generator, each revolution of the rotor causes a change in the direction of current flow. Inside electrical power-generating plants, steam turbines or gas turbines spin the rotor at the high speed of 3,600 rpm. This rotation is equal to 60 times a second, which creates a change in direction of current flow at an AC frequency of 60 cycles, commonly referred to as 60 hertz.

33.12 ELECTRICAL CIRCUITS

Power is supplied to a HVACR unit by the electrical power system. The power systems will have one or more electrical circuits that are used to deliver electrical power to the HVACR equipment. Electrical power systems have three essential requirements and one optional requirement:

- A source of power (could be a transformer)
- An electrical load device
- An electric circuit: a path for the current to flow
- (Optional) A switch to control the flow

Power Source

The electrical power source can be provided by a battery or from the building's central electrical system. Batteries supply DC power, while most buildings will have AC power

PLUG, SOURCE OF ELECTRONS

transmitted from the local utility company. Transformers will step down the high voltage generated at the electrical power-generating plant to the lower voltage required for residential or commercial use. Rectifiers will convert AC power into DC power, while inverters will do just the opposite and convert DC power into AC power.

Electrical Loads

A load is any electrical device that requires power to operate. Electric loads convert electricity into useful work. The most common loads for HVACR systems are electric motors. Motors drive the compressors, fans, and pumps. Motors also drive dampers and zone valves. Many other electrical components require power, such as resistance heaters and solenoid valves.

Path for Current to Flow

There must be a path for the current to travel (Figure 33-16). Every electric circuit has at least two wires, often indicated as line terminals L1 and L2. For this illustration, these would be the two prongs on the plug. For there to be a complete circuit, the path of the electricity flows through one wire of the electric circuit, passes through the load, and returns through the other wire of the electric circuit.

Switches

The switch is a device to turn the load on and off. The switch may be manually operated, such as turning on the lights when entering a dark room. Or the switch may be automatic, such as a thermostat that turns a unit on and off in response to the surrounding temperature. Generally a switch will have two positions, open or closed. A switch is referred to as closed when it allows current flow (Figure 33-17). A switch is referred to as

Figure 33-17 A closed circuit with current flowing through the load.

open when it is breaking current flow (Figure 33-18). These terms come from the operation of early knife-blade switches (Figure 33-19).

33.13 ELECTRICAL CIRCUIT OPERATION

Figure 33-20 shows a simple circuit consisting of a source, a path, and a load. A complete circuit has continuity; it has a continuous path from the source to the load and back from the load to the source. A break anywhere in the circuit

Figure 33-18 No current flows in an open circuit.

Figure 33-19 The terms *open* for “off” and *closed* for “on” describe the positions of a knife-blade switch; they are used today when describing the position of all types of switches in electrical circuits.

will keep current from flowing and prevent the load from operating (Figure 33-21). Switches can be added to a circuit to control when the circuit operates and when it does not operate. If the circuit path must pass through a switch, the switch can break the circuit and keep the load from functioning or make a complete circuit and allow the load to function (Figure 33-22).

An open circuit is a circuit without a complete path. Any break, or opening, in the circuit will keep it from operating. A short circuit is a circuit without a load. A short circuit has a power source and a complete path, but no load to do useful work. Without a load, current flow through the circuit is so high that both the source and the circuit conductors overheat.

Figure 33-20 A simple electric circuit using a battery power source and a lightbulb for the load.

Figure 33-21 A break in the circuit stops electron flow.

TECH TIP

An electrical circuit that contains a source and path without a load is called a short circuit. A circuit that contains a source and load without a path is called an open circuit. Sometimes people refer to any circuit that does not function as having a short. This is an improper use of the term. An open circuit is one that does not work. A short circuit is one that will trip the power breaker or cause something to overheat and possibly catch fire.

Figure 33-23 Four lights wired in series.

There are three types of path arrangements for circuits:

1. The series circuit, which allows only one path for the current to flow
2. The parallel circuit, which has more than one path
3. The series parallel circuit, which is a combination of series and parallel circuits

33.14 SERIES CIRCUITS

In a series circuit, components are connected along a single path and every device must function for the circuit to be complete. If one lightbulb in a series circuit burns out, then the circuit is broken and none of the lights will come on.

Current Flow in Series Circuits

In a series circuit, there is only one path for the current to follow. The power must pass through each electrical device in succession in that circuit to go from one side of the power supply to the other. An example of a series circuit is shown in Figure 33-23, where four lights are placed end to end in a single circuit. The current in a series circuit is the

(a)

(b)

Figure 33-24 Five lights wired in series.

same throughout the entire circuit because there is only one path for the electrons to take. Every device in a series circuit affects the current flow of the entire circuit.

Voltage and Resistance in Series Circuits

The voltage used by each device in the circuit is proportional to its resistance; devices with a higher resistance receive more voltage, while devices with a lower resistance receive less voltage. As an example, a fifth light bulb of identical resistance is placed in the series circuit just described and the current is allowed to remain the same at 1 amp (Figure 33-24). Notice that the voltage at each lightbulb has been reduced from 3 volts to 2.4 volts.

Because of this nonuniform voltage, loads are seldom wired in series with other loads in the HVACR industry. Motors are designed to operate at specific voltages, such as 120 V, and therefore cannot be wired together with other motors in series. Instead, usually there is only one load controlled by a series of switches, as shown in Figure 33-25. In this diagram, the 120 V power supply terminals are indicated with the symbols L1 and L2. The one load is a compressor motor. The switches placed in series with the compressor motor are used to control its operation. The thermostat is the operating control, and the other switches are all safety switches. The operating control is the switch that turns the circuit on and off during normal operation. Each safety switch checks for a specific operation condition that would be dangerous either to the equipment or to the user. If any one of the switches opens, the compressor will shut down. In a series circuit, all switches must be closed for current to flow through the circuit. The functions of the switches in this circuit are as follows:

- A thermostat used as an operating control is placed in series with the compressor motor to start and stop the compressor in response to temperature.

**Figure 33-25** Series circuit with three switches and one load.

- The low-pressure switch senses compressor suction pressure and opens on a drop in pressure. It is set to cut out at a protective low-pressure limit but remains closed at normal operating pressures.
- The high-pressure switch senses the compressor discharge pressure and opens on a rise in pressure. It is set to open at a protective high-pressure limit but remain closed at normal operating pressure.

33.15 PARALLEL CIRCUITS

In a parallel circuit, components are connected so that each has its own circuit. If all the lightbulbs in a parallel circuit are burned out except one, that one good light bulb will still come on.

Current Flow in Parallel Circuits

A parallel circuit has more than one path for current flow. The current for each load depends upon the resistance of that load. Loads with less resistance have more current flow; loads with more resistance have less current flow. Figure 33-26 illustrates a parallel circuit with three loads.

**Figure 33-26** Parallel circuit with three loads in parallel.

Notice that the current for each load does not have to pass through any other loads because each load has its own individual path. If one load is broken or removed, the other loads will continue to operate because they have their own paths.

Voltage in Parallel Circuits

The voltage to each load is the same in a parallel circuit because each circuit has its own independent connection to the power source. In HVACR equipment, parallel circuits are used to supply the same voltage to each load.

33.16 COMPARISON OF SERIES AND PARALLEL CIRCUITS

The characteristics of series and parallel circuits are opposite in every respect.

- In a series circuit, the current stays the same.
 - In a parallel circuit, the current changes with each load.
- In a series circuit, the voltage changes with each load according to its resistance.
 - In a parallel circuit, the voltage stays the same.
- In a series circuit, the load with the highest resistance receives the most voltage.
 - In a parallel circuit, the load with the lowest resistance receives the most current.
- In a series circuit, the overall circuit resistance increases as loads are added.
 - In a parallel circuit, the overall circuit resistance decreases as loads are added.
- In a series circuit, the overall circuit current decreases as loads are added.
 - In a parallel circuit, the overall circuit current increases as loads are added.

Roads can be used to illustrate the difference between series and parallel circuits. A series circuit is like a single, lane road with no passing lanes. There is only one way for all vehicles to get from one end of the road to the other, and all vehicles can only travel as fast as the slowest vehicle. Adding more distance to the road makes everyone's trip take even longer because there is more road to travel to get from one end to the other.

A parallel circuit is like a road with more than one lane. More vehicles can travel from one end of the road to the other at the same time because there is more than one path. Because there is more than one lane, all vehicles do not have to travel at the same speed. The speed in each lane is controlled by the conditions in that lane. Adding lanes increases the number of vehicles that can travel at one time and reduces the time it takes to move from one end of the road to the other.

33.17 SERIES PARALLEL CIRCUITS

A series parallel circuit, as the name implies, combines both series and a parallel arrangements of electrical devices. A typical series parallel circuit is shown in Figure 33-27. Most

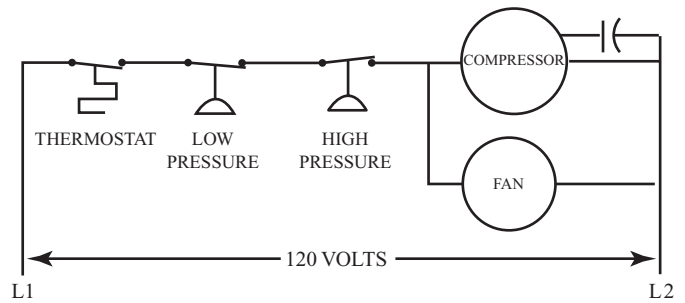

Figure 33-27 In this series parallel circuit, the fan and compressor are in parallel with each other but in series with switches.

equipment is wired with series parallel circuits. The most common use of series parallel circuits is to have several circuits in parallel with each other, with each circuit containing several devices in series. Typically each individual circuit in a series parallel arrangement has one load and one or more switches in series with the load. This allows full voltage to all loads while still maintaining control using the switches that are in series with the loads.

33.18 RELATIONSHIP OF VOLTAGE, RESISTANCE, AND CURRENT

It is useful for technicians to understand the relationship between voltage, resistance, and current. A change in one variable will affect the others. The balance shown in Figure 33-28 is a simple way to visualize the relationship between these three variables. Resistance and current are balanced on top of voltage. With voltage remaining the same, if resistance goes up, current will go down (Figure 33-29). On the other hand, if resistance goes down, current will go up (Figure 33-30).

Figure 33-28 The relationship between current and resistance can be visualized as a balance.

Figure 33-29 When the resistance increases, the current decreases.

Figure 33-30 When the resistance decreases, the current increases.

Figure 33-31 If the resistance stays the same, the voltage and current go up and down together.

Figure 33-32 For the current to stay the same, the resistance and voltage must go up and down together.

The same relationship is also true if resistance or current remain the same. Using the same principle as the balance beam, if the resistance remains the same, then voltage and current go up and down together (Figure 33-31), and if current remains the same, then voltage and resistance must also go up and down together (Figure 33-32).

33.19 OHM’S LAW

Ohm’s law is the relationship between the voltage, current, and resistance in an electrical circuit. Ohm’s law stated in simple terms is 1 V applied across a resistance of 1 Ω will produce a current of 1 A. This can be written as the mathematical formula: $E = IR$. If two of the values are known, the remaining value can be calculated. Figure 33-33 shows the three forms Ohm’s law can take, depending upon the unknown value.

Figure 33-33 Ohm’s law formulas.

Characteristic	Units	Written Formula	Symbolic Formula
Potential	Volts	voltage = current × resistance	$E = I \times R$
Current	Amps	amps = volts divided by ohms	$I = E/R$
Resistance	Ohms	ohms = volts divided by amps	$R = E/I$

TECH TIP

It should be noted that Ohm’s law does not apply to most AC circuits. The flow of current in AC circuits can be influenced by inductive reactance and capacitive reactance. Magnetic coils of wire produce an induced voltage that opposes current changes in an AC circuit. This has the effect of reducing the current flow through the circuit. As a result, Ohm’s law cannot be applied to any AC circuit that contains a capacitor or magnetic coil. The only AC circuits that work correctly with Ohm’s law are purely resistive circuits, such as electric heaters. The combined effect of resistance, inductive reactance, and capacitive reactance is called impedance. The Ohm’s law formulas will work with AC circuits if the impedance is calculated and substituted in the formulas for resistance.

The following examples illustrate simple applications of Ohm’s law.

EXAMPLE 33-1: SOLVING FOR CURRENT

The circuit in Figure 33-34 has a power source of 24 V and a load with a resistance of 8 Ω. Determine the amp draw of the circuit.

$$I = \frac{E}{R}$$
$$I = \frac{24 \text{ V}}{8 \Omega}$$
$$I = 3 \text{ A}$$

33.20 OHM'S LAW CALCULATIONS FOR A SERIES CIRCUIT

The calculations in the previous section used only one load. When a circuit has more than one load, the values can be different for each load in the circuit. The formulas used to calculate the total circuit resistance, current, and voltage depend upon whether the circuit is a series or parallel circuit.

Series Circuit Resistance

The total resistance of a series circuit is the sum of all the individual resistances. This is expressed in symbols as:

$$R_T = R_1 + R_2 + R_3 + R_4$$

For example, the total resistance of a circuit with resistances of 4 Ω, 5 Ω, and 6 Ω is found by adding the three resistances together: 4 Ω + 5 Ω + 6 Ω = 15 Ω total circuit resistance (Figure 33-37).

Series Circuit Current

The current flowing through a series circuit is the same for each load in the circuit. To determine the current in a series circuit, divide the total circuit resistance into the voltage applied to the circuit. For example, if 30 V is applied to a circuit with resistances of 4 Ω, 5 Ω, and 6 Ω, the circuit current is found by adding the resistances and dividing the sum into 30 V: 30 V / (4 Ω + 5 Ω + 6 Ω) = 2 A. Since the current in a series circuit is the same throughout the circuit, the current for all of the resistances is 2 A (Figure 33-38). This is expressed in symbols as:

$$I_1 = I_2 = I_3 = I_4$$

Series Circuit Voltage

Although the current stays the same throughout a series circuit, the voltage across each load in a series circuit is proportional to its resistance. Loads with different resistances receive different voltages. The sum of the individual voltages equals the total voltage applied to the circuit. The voltage drop across each resistance can be calculated by multiplying the circuit current times the individual resistance. The series circuit with a current draw of 2 A and resistors of 4 Ω,

Figure 33-37 The total resistance of a series circuit is the sum of all the individual resistances.

Figure 33-38 The current is the same throughout a series circuit.

Figure 33-39 The voltage drop across each load in a series circuit is proportional to its resistance.

5 Ω , and 6 Ω would have voltage drops of 8 V, 10 V, and 12 V: $2 \text{ A} \times 4 \Omega = 8 \text{ V}$, $2 \text{ A} \times 5 \Omega = 10 \text{ V}$, $2 \text{ A} \times 6 \Omega = 12 \text{ V}$. The sum of the individual voltages equals the applied circuit voltage: $8 \text{ V} + 10 \text{ V} + 12 \text{ V} = 30 \text{ V}$ (Figure 33-39). This is expressed in symbols as:

$$E_T = E_1 + E_2 + E_3 + E_4$$

33.21 CALCULATIONS FOR A PARALLEL CIRCUIT

Calculations for a parallel circuit are different than those used for series circuits. In a parallel circuit, the voltage across each of the components is the same, and the total current is the sum of the currents through each component.

Parallel Circuit Voltage

The voltage to each load in a parallel circuit is equal to the applied circuit voltage (Figure 33-40). This is expressed in symbols as:

$$E_T = E_1 = E_2 = E_3 \dots$$

Parallel Circuit Current

The current draw for a parallel circuit is determined for each of its parts. Use the standard $I = E/R$ form of Ohm's law to

Figure 33-40 The voltage is the same to all loads in a parallel circuit.

determine the current draw through each individual resistance. For example, a parallel circuit with an applied voltage of 30 V and resistances of 4 Ω , 5 Ω , and 6 Ω would have individual current draws of 7.5 A, 6 A, and 5 A: $30 \text{ V} / 4 \Omega = 7.5 \text{ A}$, $30 \text{ V} / 5 \Omega = 6 \text{ A}$, $30 \text{ V} / 6 \Omega = 5 \text{ A}$. The current consumed by the entire parallel system is the sum of the individual currents. $7.5 \text{ A} + 6 \text{ A} + 5 \text{ A} = 18.5 \text{ A}$ total circuit current (Figure 33-41). This is expressed in symbols as:

$$I_T = I_1 + I_2 + I_3 \dots$$

Parallel Circuit Resistance

The total resistance of a parallel circuit gets smaller as more resistances are added. This is because each load in parallel creates another current path, making it easier for electrons to flow. Another way to visualize this is to examine the

Figure 33-41 The total circuit current in a parallel circuit is the sum of the individual currents.

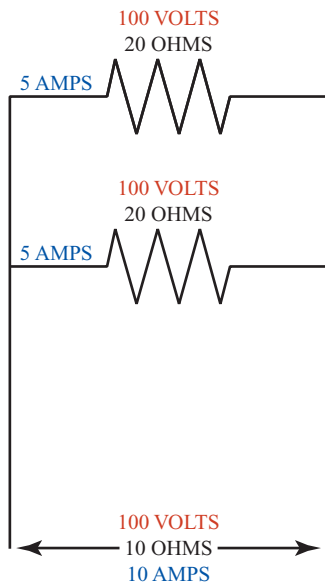

Figure 33-42 The total resistance of a parallel circuit with multiple identical resistances can be found by dividing the value of one resistor by the number of resistors.

relationship between current and resistance. Since voltage = current \times resistance, for the current to increase without increasing the voltage, there must be a decrease in resistance. For example, a 20 Ω resistor wired across 100 V would draw 5 A: $100 \text{ V} \div 20 \Omega = 5 \text{ A}$. Two 20 Ω resistors wired in parallel across 100 V would each draw 5 A. The total circuit current would be 10 A, $5 + 5$. The total circuit resistance can be calculated using Ohm's law as $100 \text{ V} \div 10 \text{ A} = 10 \Omega$. In other words, the total resistance for two identical loads is *half* the resistance of one load by itself. Similarly, the total resistance of *any* parallel circuit containing several loads of identical resistance value in parallel can be found by dividing the resistance value for any one load by the number of loads (Figure 33-42).

The formula is more complicated for parallel circuits with different value resistances. If there are only two resistances, the total resistance can be calculated by a formula called "product over the sum":

$$R_T = \frac{(R_1 \times R_2)}{(R_1 + R_2)}$$

For example, to find the total resistance of a parallel circuit with one resistance of 12 Ω and one resistance of 10 Ω :

$$\begin{aligned} R_T &= \frac{(R_1 \times R_2)}{(R_1 + R_2)} \\ R_T &= \frac{(12 \Omega \times 10 \Omega)}{(12 \Omega + 10 \Omega)} \\ R_T &= \frac{120}{22} \\ R_T &= 5.4 \Omega \end{aligned}$$

If there are more than two resistances, use the following formula and solve for R_T :

$$\frac{1}{R_T} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3}$$

Note that this formula is actually solving for the reciprocal of R_T . The answer must be inverted to find R_T . For example, a parallel circuit with resistances of 4 Ω , 5 Ω , and 6 Ω :

$$\begin{aligned} \frac{1}{R_T} &= \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} \\ \frac{1}{R_T} &= \frac{1}{4} + \frac{1}{5} + \frac{1}{6} \\ \frac{1}{R_T} &= \frac{15}{60} + \frac{12}{60} + \frac{10}{60} \\ \frac{1}{R_T} &= \frac{37}{60} \\ R_T &= \frac{60}{37} = 1.6 \Omega \end{aligned}$$

R_T will always be smaller than the smallest resistor in the problem. In the example, $R_T = 1.6 \Omega$, which is smaller than 4 Ω , the lowest resistance in the problem.

TECH TIP

Finding a common denominator can get messy when the values are not simple numbers. An easy way to work parallel resistance problems is to use a calculator with a reciprocal key and memory. Enter each resistance followed by the reciprocal key (1/x). Then push the memory plus key (M+) to add the results of each process into memory. Last, push the memory recall key (MR) to display the sum, and push the reciprocal key to show the answer.

33.22 CALCULATIONS FOR A SERIES PARALLEL CIRCUIT

Most circuits are not simple series or parallel circuits but a more complex combination of the two. To analyze a series parallel circuit, solve sections of the circuit that can be solved using the available formulas and then consider those sections as one load. For example, the circuit in Figure 33-43 has two 20 Ω loads in parallel with each other. However, both loads are in series with the 5 Ω load. First calculate the resistance of the two parallel 20 Ω loads, $20 \Omega / 2 = 10 \Omega$. The circuit can now be considered a series circuit with one 10 Ω

Figure 33-43 Series parallel circuit with a parallel block.

Figure 33-44 Series parallel circuit with a series block.

load and one 5 Ω load. Adding the two together gives you a total resistance of 15 Ω for the circuit. The most expedient solution to this problem was to apply the parallel formula first and then the series formula; however, the formulas used and the order in which they are executed depend upon the particular series parallel circuit being studied.

If the same three components are rearranged as in the diagram in Figure 33-44, the approach and the answer will change. In this diagram, a 20 Ω load and the 5 Ω load are in series with each other and another 20 Ω load is in parallel to both of them as a group. Now it is necessary to use the series formula first to find the total resistance of the 5 Ω and 20 Ω loads, which would be 25 Ω. The problem is now a parallel problem with one 20 Ω load and one 25 Ω load. Using the product over the sum formula: $(25 \times 20)/(25 + 20) = 500/45 = 11.11 \Omega$. When circuits advance past two or three loads, several series or parallel blocks may be possible, and there will generally be more than one approach to the solution.

33.23 WATTS

The watt is the unit used to measure the rate of electrical work. The watt is an electrical rate of work equal to 1 joule per second (J/S). A watt is the amount of work done when 1 amp flows with a potential difference of 1 volt. The formula for calculating watts is: watts = volts × amps. This is shown symbolically as $P = IE$. If any two factors are known, the third can be calculated using one of the formulas in Figure 33-45.

EXAMPLE 33-4: SOLVING FOR POWER

In Figure 33-46, find the wattage of an electric heater with a current draw of 8 A on 120 V:

$P = IE$
 $P = 8 \text{ A} \times 120 \text{ V}$
 $P = 960 \text{ W}$

EXAMPLE 33-5: SOLVING FOR CURRENT

In Figure 33-47, find the current draw of a 60 W, 120 V heater:

$I = P/E$
 $I = 60 \div 120$
 $I = 0.5 \text{ A}$

EXAMPLE 33-6: SOLVING FOR VOLTAGE

In Figure 33-48, find the voltage applied to an 800 W electric heater drawing 10 A:

$E = P/I$
 $P = 800 \text{ W}/10 \text{ A}$
 $E = 80 \text{ V}$

33.24 COMBINING OHM’S LAW AND THE POWER FORMULA

Occasionally, the two known values will not work with either Ohm’s law or the power formula. To solve this, values for volts, ohms, amps, or watts may be stated in terms of one

Figure 33-48 Calculating the voltage using the power formula if amps and watts are known.

formula and substituted in another formula. For example, suppose you needed to find the voltage for a device with a known resistance and wattage. These two values will not work in either Ohm's law or the power formula. However, the value P/E can be substituted for I in Ohm's law, so it can be rewritten $E = (P/E)R$. This can be rearranged algebraically as $E = \sqrt{PR}$. Now the value for voltage can be found by multiplying watts times resistance and taking the square root of the product. Figure 33-49 shows all the variations of the Ohm's law and power formulas that can be produced using the two formulas. The formulas that contain either squared values or square roots of values are the result of algebraic combinations of Ohm's law and the power formula.

In Figure 33-50, find the wattage lost through a conductor with 50 Ω of resistance carrying 3 A:

$$P = I^2 \times R$$

$$P = 3^2 \times 50$$

$$P = 9 \times 50$$

$$P = 450 \text{ W lost through the conductor}$$

TECH TIP

It should be noted that the power formula cannot be directly applied to most AC circuits. The flow of current in AC circuits can be influenced by inductive reactance and capacitive reactance. Magnetic coils of wire produce an induced voltage that opposes current changes in an AC circuit. This has the effect of causing the voltage and current to peak at different times, so that the delivered power is less than the product of volts and amps. Three-phase power has three different currents operating at one time. A measurement of one does not accurately indicate the current used by the device. The only AC circuits that work correctly with the power formula are single phase, purely resistive circuits, such as electric heaters.

UNIT 33—SUMMARY

Electricity is the flow of free electrons. Electrons are negative subatomic particles that exist on the outside of an atom. Electron flow is a chain reaction, with electrons moving from atom to atom. Conductors have many electrons but only a few in their outer orbit. Insulators have several electrons in their outer orbit. Electron flow in one direction is called direct current. This type of current flow is used with battery-powered devices. Alternating current reverses directions at regular intervals. Alternating current is used for power distribution because of its ability to be easily transformed to different voltage levels, allowing for high-voltage transmission and reducing line loss.

Electrical potential is the ability to produce an electrical current; it is measured in volts. Electrical current is the rate of electron flow; it is measured in amps. Resistance opposes the flow of electrons; it is measured in ohms. Electrical work is affected by both the potential and the current flow; it is measured in watts.

A circuit is composed of a source of electrical power, a path for electrons to flow, and a load to convert the electrical energy into useful work. Resistance and current move opposite to one another: when the resistance goes up, the current goes down. A series circuit has only one path for electron flow. The current in a series circuit stays the same throughout the circuit, and the voltage drop across loads in series is proportional to their resistance. The voltage stays the same in a parallel circuit, and the current for each load is determined by that load's resistance, not the entire circuit resistance. Adding loads in series increases the circuit resistance; adding loads in parallel decreases the circuit resistance.

Ohm's law and the power formula can be used to determine any of the commonly measured circuit characteristics: voltage, amps, ohms, or watts. If any two characteristics are known, the others can be calculated using Ohm's law and the power formula. The basic formula for Ohm's law is $E = IR$. The basic power formula is $P = IE$. Ohm's law and the power formula are not applicable to alternating current circuits, which have inductive or capacitive loads.

UNIT 34

Alternating Current Fundamentals

OBJECTIVES

After completing this unit, you will be able to:

1. identify the different types and categories of electricity and electrical power systems used in the HVACR industry.
2. explain the basis for magnetic induction in coils and transformers.
3. explain how capacitors work in AC circuits.
4. discuss the uses of single-phase and three-phase power.
5. describe how electrical power is generated.
6. state the importance of overcurrent protection.

34.1 INTRODUCTION

The electrical power provided to residential and commercial customers is alternating current (AC) with a frequency of 60 cycles (hertz). AC power flowing through an electrical circuit has unique characteristics that must be understood by the HVACR technician prior to installing or servicing equipment. It is also important to note that residential service will be very different from commercial service. Residential service requires lower voltage and single-phase power. Commercial systems utilize higher voltages and three-phase power. Therefore, the electrical connections, the types of motors, and the electrical code requirements will not be the same.

This unit shows how resistance, inductance, capacitance, and impedance affect the operation of AC circuits. From this, the HVACR technician can understand the relationship of voltage to current in an AC circuit. Single-phase and three-phase power is also explained and the differences between the two made clear. In addition, there are examples of power-distribution arrangements with the appropriate line voltage connections illustrated for both residential and commercial service. After reviewing this unit, the HVACR technician will have a good understanding of AC circuit behavior and power distribution.

34.2 TYPES OF POWER SOURCES

There are two common types of power:

- Direct current (DC)
- Alternating current (AC)

Many electrical testing instruments operate on DC power. This is because the most common source of direct current is the battery. Batteries allow test instruments to be portable and convenient to use. DC power can also be used for control systems and on solid-state modules for defrost and overcurrent protection. For these applications, the DC power is often converted from AC power through a rectifier instead of using batteries.

Alternating current is the most common source of power for most HVACR systems. AC power is generated by all the power companies. In residences, 120 V AC is used to power most small appliances. Larger appliances such as electric stoves and residential air-conditioning units use 240 V. The power company supplies residential users with 240 V over the incoming lines. A portion of it is tapped to supply the 120 V requirements. Commercial and industrial customers normally use higher voltages in single-phase and three-phase systems.

TECH TIP

In the United States the AC frequency supplied by power companies is normally 60 cycles. Many foreign countries supply power at 50 cycles. It is important to use equipment that is designed to operate at the proper frequency.

34.3 MAGNETISM

The theory of electron flow was discussed in Unit 33. Some materials (conductors) have more free electrons, while others (insulators) have few or no free electrons. These electrons have a spinning motion. When an equal number of electrons spin in opposite directions, they tend to cancel each other out. However, if more electrons spin in one direction than the other, a magnetic field is developed. The materials that exhibit this behavior are called magnets.

A force called a magnetic field transmits outward in all directions from magnetic materials. The invisible lines of force are referred to as magnetic flux and are shown radiating from the magnet in Figure 34-1. Lines of force are always considered to leave the north pole and enter the south pole of a magnet in continuous loops. Like poles repel each other, and opposite poles attract (Figure 34-2).

Since flux will choose the path of least resistance (called reluctance), the field is scattered in Figure 34-1 because air has a high reluctance. However, if an iron bar with

Figure 34-1 Invisible magnetic lines of force.

Figure 34-2 Like poles repel each other and opposite poles attract.

a low reluctance is placed between the two ends of the magnet, the flux will concentrate through it, and this force will draw the iron toward the magnet (Figure 34-3).

Electromagnetism and Induced Voltage

When current passes through a conductor, a magnetic field is produced (Figure 34-4). The magnetic field has no poles, but, similar to magnets, there is a continuous loop with a specific direction. The left-hand rule is used to determine the direction of rotation of the flux around the conductor. Imagine the conductor held in your left hand with your thumb pointing in the direction of current flow. Your fingers will align in the direction of the flux (Figure 34-5).

There is another phenomenon that is exhibited with conductors. If the conductor is moved through a magnetic field, a voltage is induced in the conductor (Figure 34-6). The polarity of the induced voltage is affected by which

Figure 34-3 Magnetic flux concentrates in the iron core, and this force pulls the iron toward the magnet.

Figure 34-4 Electrons flowing through a straight wire form a weak magnetic field around the wire.

Figure 34-5 Left-hand rule for determining the direction of the flux rotation around a wire.

Figure 34-7 When the wire is coiled, the weak magnetic field around each section of wire combines to form a stronger magnetic field around the coil.

direction the conductor is moved through the field (up or down) and the direction of the magnetic field.

34.4 MAGNETIC INDUCTION IN COILS AND TRANSFORMERS

The magnetic field created by current passing through the conductor will intensify if the conductor is coiled (Figure 34-7). If an iron bar is placed inside the coil, as in Figure 34-8, the current flow through the coil will concentrate the lines of force through the iron bar as previously shown in Figure 34-3. This creates a north and south polarity. This polarity can be reversed by changing the direction of current flow through the coil.

Solenoid Valves

A good example of this type of magnetic induction is the operation of solenoid valves. Solenoid valves are electrically operated valves that open and close automatically by energizing or de-energizing a coil of wire (Figure 34-9). They are used in many applications, such as in refrigeration systems to start and stop the flow of refrigerant. They are used as emergency fuel shutoff valves in boilers. They are used to control the flow of hot or cold water in a washing machine.

A refrigeration solenoid valve is shown in Figure 34-10. When the coil is energized, the valve will open, and when the coil is de-energized the valve will close. The movable plunger acts similarly to the iron core described in Figure 34-7. When the coil is energized, the plunger, which has much less reluctance than the air, will provide a path for the flux. The plunger is then drawn upward toward the coil (similar to the

Figure 34-8 The addition of an iron core to the coil concentrates the magnetic lines of force.

Figure 34-9 A typical coil that would be used for a solenoid valve.

Figure 34-10 The solenoid valve coil is de-energized and the valve is closed.

Figure 34-11 The solenoid valve coil is energized and the valve is open.

iron bar being pulled toward the magnet in Figure 34-3), and the valve will open as shown in Figure 34-11. When the coil is de-energized, there is no magnetic force to hold it in the coil and it moves downward to close the valve.

Relays and Contactors

This same principle is applied to the construction of relays and contactors as well. These act as automatic switches to turn loads on and off. In the resting position, gravity keeps the contacts separated. Referring to Figure 34-12a, when

Figure 34-12 (a) Coil de-energized; (b) coil energized.

current flows through the coil, the iron core is magnetized and is drawn into the coil. This raises the iron core and changes the position of the relay contacts, as shown in Figure 34-12b.

Transformers

A different application of the induction principle is used in the construction of a transformer, which has no moving parts. Transformers are used to increase or decrease incoming voltages to meet the requirements of the load. Transformers are used to step down the line voltage to 24 V for the controls used in many HVACR units. Transformers contain a single iron core that is wrapped with two separate coiled conductors known as primary and secondary windings (Figure 34-13). When AC voltage is applied to the primary winding, the resulting lines of force are carried through the core. These lines create a current flowing through the secondary winding, inducing a voltage in that winding.

There are two types of transformers: step-down transformers and step-up transformers (Figure 34-14). Step-down transformers are often used to reduce line voltage required for motor starters to lower voltages for the controls. The

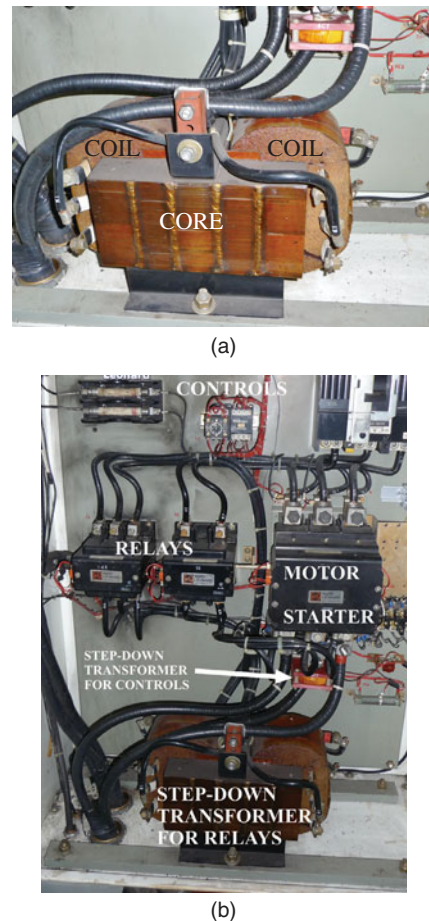

Figure 34-13 (a) A large transformer for an AC chiller unit; (b) the large transformer steps down line voltage to relay voltage, and the small transformer steps down relay voltage to control voltage; (see next page) (c) a small, low-voltage transformer for a control circuit board; (d) transformer for starting relay for a fan blower motor.

440 line voltage supplied to the motor starter shown in Figure 34-13a,b is stepped down by the large transformer to a lower voltage for the relays and then further stepped down by a second smaller transformer to a lower voltage for the controls.

The amount of voltage induced in the secondary winding depends on the ratio of the number of turns in the primary winding to the number of turns in the secondary winding (Figure 34-15). As an example, a primary voltage of 1 volt with four turns would induce a voltage of 0.25 volts to one turn in the secondary or 0.5 volts to two turns in the secondary.

TECH TIP

The word *inductance* means “to cause or create.” The electricity flowing through a coil of wire induces a magnetic field that causes another electric current to flow in a parallel coil. There is no electrical-mechanical connection between the windings of an induction device such as a transformer. Each winding is completely separate. The only time the two windings are connected is when the transformer has been overheated and the wiring insulation has broken down.

34.5 MAGNETIC INDUCTION IN GENERATORS AND MOTORS

Magnetic induction, demonstrated in Figure 34-16, is used to generate voltage for commercial and residential use. Electrical current is produced by moving coils of wire through a magnetic field. The amount of voltage produced is proportional to how fast the coils of wire move and how strong the magnetic field is. Electrical current can be produced by either a generator or an alternator. A generator rotates coils of wire inside a magnetic field, while an alternator rotates a magnetic field inside coils of wire. Either way, free electrons in the coil of wire are pulled by the magnetic field, generating electricity. Figure 34-17 shows current being generated through a single loop of wire rotating in a fixed magnetic field. As the loop turns clockwise through the magnetic field, a flow of electrons is established in the wire. Alternating current is generated because the loop cuts the lines of force first

Figure 34-16 Current is induced in a coil of wire rotating in a magnetic field.

in one direction and then in the other as it makes a complete revolution. Notice that the wire near the north pole is always negative and the wire near the south pole is always positive. However, the red half of the wire is near the north pole during the first half cycle and near the south pole during the last half cycle. This means that the red wire is negative during the first half cycle and positive during the last half cycle.

AC Motors

This induction principle is also applied to the construction of AC motors (Figure 34-18). The basic motor has two coils wrapped around stationary cores called stator poles. As AC current flows through the coils, the stator poles are magnetized. The stator field induces an opposing field in the rotor and the principle of attraction and repulsion causes the motor to run.

TECH TIP

Sixty-cycle current can create a low-frequency hum in some motors and transformers. This hum is a result of the frequency of current that passes through the coil. Sometimes this noise can be very disturbing to the residents. Occasionally the sound is amplified because the motor or transformer is not tight on its mounting brackets. Secure the motor tightly to attempt to reduce the sound. If the sound can be tracked to a vibrating sheet-metal component, that component may be secured using a pop rivet or sheet-metal screw to reduce the sound level.

Figure 34-18 When ac power is applied to the coils of a motor, the rotor turns.

Figure 34-19 One cycle of alternating current.

34.6 SINGLE-PHASE VOLTAGE

Alternating current flow continuously reverses direction to produce a sinusoidal waveform that alternates polarity continuously at a fixed rate or frequency. The number of times per second the polarity is reversed is the frequency expressed in hertz (Hz), or cycles per second. Alternating current is produced by rotating a coil within the magnetic field to produce an output voltage. Figure 34-19 is a diagram of a single cycle that is repeated 60 times per second (60 Hz), on a continuous basis. This is called single-phase voltage.

Figure 34-20 Three-phase alternating current is produced when three coils rotate inside of a magnetic field.

Single-phase power is commonly used for residential and small commercial systems. For larger motors, generally 5 hp and above, three-phase power is normally used. This requires the addition of one more conductors to the generator, as shown in Figure 34-20. The three conductors are positioned 120° from each other.

A diagram of the three-phase waveforms is shown in Figure 34-21. They have the same shape, but they are 120° out of phase with each other.

34.7 PHASE SHIFT

In working with AC power, certain characteristics affect the power calculation, $E \times I$, which are known as phase shift factors. The phase shift factors relate to the following:

- Resistive circuits
- Inductive circuits
- Capacitive circuits

34.8 RESISTIVE CIRCUITS

The resistive circuit (Figure 34-22) contains at least one resistive load, such as an electric heater or lamp. The current rises and falls with the voltage and the two are considered

Figure 34-21 The three legs of power produced by a three-phase AC generator.

Figure 34-22 The AC voltage and current flow through resistance loads, like lightbulbs, at the same time.

to be synchronized, or "in phase." The maximum voltage occurs at the same time (or same phase angle) as the maximum amperage.

34.9 INDUCTIVE CIRCUITS

Motors, relays, transformers, and some other AC loads are constructed using coils of wire. These coils produce magnetism and are called inductive loads. The voltage and current in circuits containing inductive loads are phase shifted, or out of phase, sometimes as much as 90°.

In the inductive circuit, the current lags, or is out of phase with the voltage, as shown in Figure 34-23. In this circuit, the current waveform peaks 90° after the voltage

Figure 34-23 The AC voltage leads the current through inductive loads, like motors.

waveform. Because of this current lag, the measured power in an inductive circuit will always be less than the calculated power ($E \times I$). This is because measured power is an instantaneous reading, and at any particular time, one or the other or both voltage and current readings are not at their peak.

The term *power factor* is used to indicate this difference.

$$\text{power factor} = (\text{true power})/(\text{apparent power})$$

or

$$\text{power factor} = (\text{wattmeter reading})/(E \times I)$$

34.10 CAPACITORS

A capacitor is an electrical device that is used to change the phase relationship between the current and the voltage. This effect can be used to increase the starting power (torque) of an electric motor. A simple capacitor consists of a layer of insulation (a dielectric) placed between two plates of highly conductive metal (Figure 34-24).

Capacitors are broadly categorized as either polarized or nonpolarized and variable (Figure 34-25). The curved line in the symbol will represent the proper lead for some

Figure 34-24 Capacitors are made up of two plates, thin metal foil, separated by an insulation paper and rolled up together.

(a)

(b)

capacitors. DC circuit capacitors are polarized with the curved plate of the symbol indicating the negative terminal. With variable capacitors, the curved line identifies the plate that is electrically connected to the frame or adjusting mechanism. With rolled-foil types, the curved line represents the outside foil, and the lead connection on the capacitor is identified by a color band at that end (Figure 34-26a). Electrolytic polarized capacitors will have markings to indicate polarity (Figure 34-26b).

34.11 CAPACITORS IN AC CIRCUITS

A capacitor is usually connected in series with the load (Figure 34-27). Obviously, no current can flow through the capacitor because of the dielectric. Initially, the current does flow through the series circuit (Figure 34-28). When the switch is closed, the supply voltage is applied across the capacitor. At that instant, the electrons flow rapidly

Figure 34-27 A capacitor causes a phase shift, so the current leads the voltage through a capacitance circuit.

Figure 34-28 The capacitor charges when source voltage is applied. Electrons flow rapidly from the source to the first plate of the capacitor and from the second plate of the capacitor to the source, causing a current to flow through the load.

from the source to the first plate of the capacitor and from the second plate of the capacitor to the source, causing a current to flow through the load. The capacitor quickly reaches peak current. It is described as charging during this period.

Figure 34-29 As the voltage on the first plate builds to its peak, most of the electrons have flowed off of the second plate.

TECH TIP

DC capacitors have positive (+) and negative (–) terminals and must be connected to the circuit with the proper polarity. When the switch to a capacitor installed in a DC circuit is closed, current initially flows, the capacitor charges, and then current flow stops. Since there is no change in the direction of current, the capacitor remains charged but now would appear to the circuit as an open switch.

Following the initial rapid flow of electrons, the rate of current flow reduces (Figure 34-29). Figure 34-30 shows the resulting downward movement of the current waveform. As electrons leave one plate and accumulate on the other, a potential difference (voltage) begins to develop across the capacitor. This difference is created by current flow and therefore lags the current. In this circuit, which contains a resistive load, current leads the voltage by 45° (Figure 34-30).

As the supply voltage waveform crosses the baseline, the polarity across the capacitor changes and electrons leave the first plate. The capacitor discharges and the current flows through the load in the opposite direction (Figure 34-31). The capacitor continues in this manner as long as the source voltage is being applied.

Figure 34-30 Current leads the voltage by 45° .

Figure 34-31 As the voltage peaks positive and starts back down toward zero, the electrons that were piled up on the first plate quickly flow off, forming a rush of current out of the capacitor.

TECH TIP

A capacitor provides a phase shift to help an induction electric motor to start. A start capacitor added to an electric motor gives it greater phase shift for greater starting torque. Too much phase shift from an excessively large start capacitor can actually reduce some of the starting torque. Engineers have done extensive studies to determine the most appropriate size of start capacitor to optimize the starting torque. Refer to the manufacturer's literature anytime you are applying a start capacitor to an induction motor.

Capacitive Reactance

Capacitive reactance is a term used to describe a capacitor's opposition to alternating current and is somewhat like resistance that can be used to control the current in a circuit. There are two main factors that affect capacitive reactance: the frequency of the current (and voltage) and the amount of capacitance. Doubling the frequency or capacitance will reduce the reactance by half. Doubling the reactance will reduce the frequency or capacitance by half.

34.12 IMPEDANCE

Impedance is the opposition to the current flow in an AC circuit. Impedance is to an AC circuit what resistance is to a DC circuit; however, multiple impedances in a circuit cannot be

added like resistances are added in direct current because the currents through inductive, capacitive, and resistance loads in an AC circuit are out of phase with each other.

The following is an example of calculating impedance in an inductive circuit.

The formula that is used is:

$$Z = E/I$$

where

Z = impedance

EXAMPLE 34-1: SOLVING FOR IMPEDANCE USING VOLTS AND AMPS

What is the impedance of a single-phase inductive circuit having a voltage of 240 V and a current flow of 10 A?

$$Z = \frac{240 \text{ V}}{10 \text{ A}} = 24 \text{ Ohms}$$

34.13 POWER DISTRIBUTION

Almost all of the electrical power used by consumers today is alternating current. It is supplied to substations at voltages as high as 120,000 V. There it is reduced to voltages between 4,800 V and 34,000 V for distribution to areas of commercial or residential users. Most power companies are now using 23,000 V or 34,999 V. Local transformers reduce the voltage levels to suit user requirements, as shown in Figure 34-32.

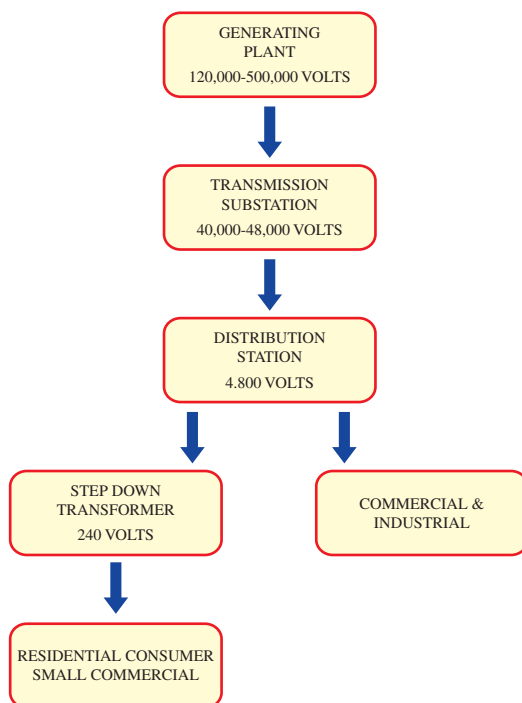

Figure 34-32 Voltage reduction in the power-distribution system.

TECH TIP

The primary reason that alternating current is used as the standard power source in commercial and residential buildings is that it is the most easily transformed from one voltage to another. Without the ability to transform power from the higher voltages used during transmission to the lower voltages used in our homes and businesses, cross-country transmission lines would have to be made with extremely large-diameter wires.

Four common low voltage systems are available to consumers:

- 240 V, single-phase, 60 Hz systems
- 240 V, three-phase, 60 Hz systems
- 208 V, three-phase, 60 Hz systems
- 480 V, three-phase, 60 Hz systems

SERVICE TIP

Although most consumer power is alternating current, DC is still used in many applications. An example is your service van. This DC can be converted to AC with a power inverter that uses an automobile's 12 V battery to produce 110 V of 60 cycle current. A power inverter is a great device to add to your service van because it allows you to run portable drill chargers and other electrical devices that normally must be plugged into a standard outlet.

34.14 ELECTRIC SERVICES

Single-phase current is used for almost all residences. Any electrical appliance that operates on 120 V power is single-phase equipment. The most common service supplied to residential and small commercial users is the 240 V, single-phase, 60 Hz system. The system uses three wires—two hot wires and one grounded neutral. A schematic diagram of this 240 V system is shown in Figure 34-33. Electric utility

Figure 34-33 Line voltage for a three-wire 240 V single-phase power supply.

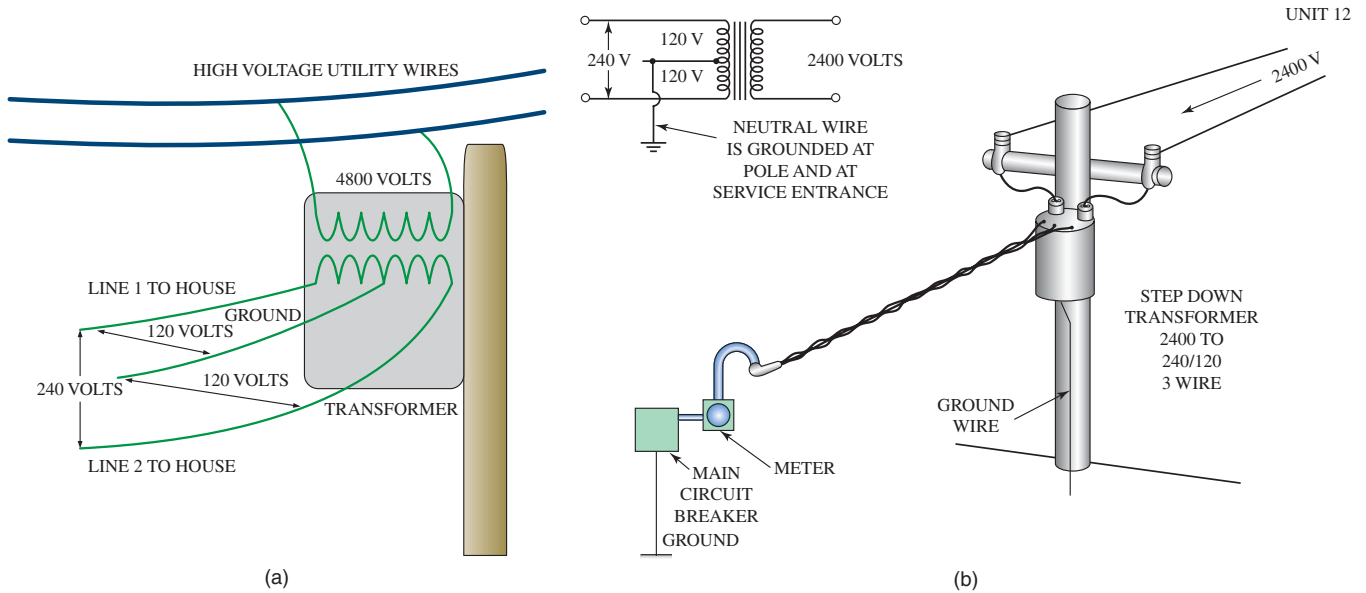

Figure 34-34 Step-down transformer for a 240 V three-wire single-phase power supply.

companies use a transformer to produce this service, as shown in Figure 34-34.

All HVACR equipment is manufactured to operate satisfactorily on voltages of plus or minus 10 percent of the rated voltage unless otherwise specified. For example, if the equipment has a voltage rating of 230 V, the equipment should be able to operate at any voltage between 207 and 253 V. HVACR equipment has a tendency to operate more satisfactorily on maximum voltage than on minimum voltage.

The electric utility attempts to maintain a voltage at the load within this plus or minus (\pm) 10 percent range. At peak load times, the line voltage may drop to near the permitted minimum. If you suspect any voltage problems, the line voltage at the HVACR load should be measured at these times.

34.15 240 V, THREE-PHASE, 60 Hz DELTA SYSTEMS

Three-phase systems are commonly used for sizable commercial and industrial installations. These transformers have three hot legs of power and one neutral leg, as shown in Figure 34-35. This type of power supply is obtained from a delta transformer secondary hookup, as shown in Figure 34-36.

Three-phase 240 V power is obtained by connecting to the three hot legs. Single-phase 240 V power can be obtained by connecting to any two of the hot legs. Single-phase 120 V power can be obtained by connecting to either of the adjacent hot legs and the midpoint neutral. Single-phase 208 V power can be obtained by connecting to the nonadjacent hot leg and the ground. This is called the wild leg.

34.16 208 V, THREE-PHASE, 60 Hz WYE SYSTEMS

These systems are common in schools, hospitals, and office buildings where 208 V three-phase motors and 120 V single-phase lighting and convenience circuits are required,

as shown in Figure 34-37. From this type of system, 208 V three-phase, 208 V single-phase, and 120 V single-phase services are available. The schematic for the wye transformer secondary hookup is shown in Figure 34-38.

higher supply voltage permits larger loads to be serviced by smaller wires. In addition, voltage drops are reduced.

SERVICE TIP

It is recommended that all motors used be rated for 208 V (not 230 V) for operation on 208 V systems.

TECH TIP

A 460 V three-phase system will draw less current than a 208 V three-phase system. For example, a 50 hp, 460 V three-phase 60 Hz motor would have a full load of 57.5 A, while the same motor at 208 V would have a full load of 122 A.

34.17 480 V SYSTEMS

The 208 V/120 V three-phase four-wire wye-connected system, shown in Figures 34-37 and 34-38, has been generally superseded in large buildings by the 480 V/277 V three-phase four-wire wye-connected system, shown in Figures 34-39 and 34-40. This improvement was made possible by the development of 277 V fluorescent lighting. Standard 460 V three-phase motors can be used on 480 V systems. Convenience outlet circuits at 120 V are provided for by 480 V/208 V or 480 V/120 V step-down transformers. The

34.18 SINGLE-PHASE VERSUS THREE-PHASE POWER

Three-phase power is most often used by large HVACR equipment operators. The following are some of the reasons:

- Individual line current for a three-phase load is approximately 58 percent of a similarly sized single-phase load. Since wire is sized by current draw, reducing the line current also reduces the wire size and voltage drop.

- There is less power loss to transformers in using it.
- Three-phase motors are smaller, less expensive, more reliable, and more efficient than single phase. They do not require special capacitors to increase their starting torque.
- Some three-phase motors have an ability to correct the phase shift caused by some other inductive loads. Large commercial consumers of electric power are often faced with a surcharge that is applied to their base electrical rate when their power consumption is out of phase. Three-phase motors can reduce or eliminate this surcharge by correcting the phase angle.

Single-phase power is used for most HVACR residential and light commercial systems. The following are some of the reasons:

- Single-phase power is more readily available than three-phase power.
- Because of the popularity of single-phase power, a larger variety of equipment types and sizes are available.
- Single-phase equipment is more readily available because it is often kept in stock at supply houses.

34.19 OVERCURRENT PROTECTION

The sizing of the electrical power wiring and overcurrent protection are important for a number of reasons, with safety being the most important. If the wiring is not large enough to carry the current, it may overheat and cause a fire. It may also become hot enough to melt the insulation, allowing the wire to come in contact with part of the equipment case, which could cause an electrical shock to anyone touching the charged metal.

The fuse and/or circuit breaker sizing are important. Proper sizing will ensure that in case of an overcurrent event the wiring is protected. This is very important because the wiring often runs through areas of homes and buildings that contain wood and other combustible building materials. If this wiring were to overheat, it could start a fire. All HVACR residential and most commercial units are located inside metal cabinets. As part of the UL certification process, these cabinets are tested to guarantee that they will withstand an internal component fire. This is to confirm their safety should an overcurrent event happen inside the unit.

Many HVACR units have name plates that list the minimum circuit ampacity and the maximum overcurrent protection ratings. If the unit does not have this information, you may locate it in the National Electrical Code or calculate it using one of several similar equations.

34.20 SIZING POWER WIRING

The *minimum circuit ampacity* (MCA) is the amperage load that the conductor must be sized at as a minimum for the equipment load. MCA is calculated using the following equation:

$$\text{MCA} = (1.25 \times \text{FLA}_1) + \text{FLA}_2 + \text{FLA}_3 + \text{FLA} \dots$$

where

MCA = minimum circuit ampacity (amperage capacity)
1.25 = a constant that increases the FLA for the motor by 25 percent

FLA_1 = the full load amps (FLA) or rated load amps (RLA) of the largest motor

$\text{FLA}_2 + \text{FLA}_3 + \text{FLA} \dots$ = the full load amps (FLA) or rated load amps (RLA) of the all the other motors

For example, find the MCA for a rooftop unit that has the following data listed on its name plate: compressor FLA 22, two fans FLA 3.5 each.

$$\text{MCA} = (1.25 \times \text{FLA}_1) + \text{FLA}_2 + \text{FLA}_3 + \text{FLA} \dots$$

$$\text{MCA} = (1.25 \times 22) + 3.5 + 3.5$$

$$\text{MCA} = 27.5 + 3.5 + 3.5$$

$$\text{MCA} = 34.5 \text{ A}$$

34.21 SIZING CIRCUIT PROTECTION AND DISCONNECTS

The maximum overcurrent protection (MOCP) is the maximum amperage rating for fuses or circuit breakers that are used to protect the system. If wiring in the circuit passes too much current, it will overheat and cause conductor failures or fires. Typically all equipment will have a listed maximum fuse or circuit breaker designation that should always be adhered to. Never use a larger fuse or breaker size than the one originally designated for the equipment. It is also important to note that a motor may be operating in an overloaded condition while the circuit itself is not, and the fuse will not open the circuit. That is why each motor is also protected separately from the circuit from an overload within its own operating range.

SERVICE TIP

HVACR-type fuses or circuit breakers must be used. These are often classified as “slow blow” because they will handle the momentary surge of current associated with starting a motor. If standard circuit breakers or fuses are used, nuisance trips may result.

UNIT 34—SUMMARY

Alternating current (AC) is the most common source of power used for most HVACR systems. The current flow reverses and changes direction at a regular interval referred to as frequency. The typical frequency is 60 times per second, designated as 60 hertz (Hz).

One important characteristic of AC power that needs to be understood is the relationship between the current and voltage in a circuit referred to as phase shift. In a purely resistive circuit, the current rises and falls with the voltage and is considered to be “in phase.” However, the current

lags the voltage in an inductive circuit, and because of this phase shift, the measured instantaneous power will be less than the calculated power. This difference is referred to as the power factor. In a capacitive circuit, the phase shift is opposite and the current leads the voltage. Another important characteristic of an AC circuit, referred to as impedance, is the opposition to the current flow.

Power-distribution systems can be single or three phase. Single-phase power is typically used for most HVACR residential and light commercial systems. Single-phase power is readily available, and there is a large variety of single-phase equipment to choose from. Three-phase power is more commonly used in commercial applications. Three-phase systems allow for reduced line current, less transformer power loss, and smaller, more efficient motors. Since either of these systems may be encountered on the job site, the HVACR technician needs to understand both single-phase and three-phase circuits.

35.1 INTRODUCTION

The terms *test instrument* and *test meter* are used interchangeably in the HVACR field to describe devices that are used to detect some aspect of an electrical system's operation. Usually they are used to determine how a system is operating or why it is not operating. This information can then be used for servicing and troubleshooting.

The types and availability of test meters have increased to the point that it can be extremely difficult to determine which meter is best for a particular application (Figure 35-1). The flood of inexpensive test meters into the market has also provided what may appear to be a cost-effective way to outfit your toolkit. However, it is important to note that many of these inexpensive test meters will not be appropriate for HVACR use. Test meters should be selected based upon the standards required for their application. Never select a meter that is not rated for the application where it will be used.

This unit provides information on some of the general standards and ratings for test meters, but this information is not intended to replace any operating instructions provided by the meter's manufacturer. Always read and follow all manufacturers' operating and safety instructions; failing to do so can damage the equipment and may result in your being injured.

35.2 SAFETY STANDARDS

The two principal government agencies that oversee workplace safety are OSHA (U.S. Occupational Safety and Health Administration) and NIOSH (National Institute for Occupational Safety and Health). OSHA sets and enforces the rules, while NIOSH provides helpful information on workplace safety.

TECH TIP

An eighty-eight-page electrical safety handbook, *Electrical Safety—Safety and Health for Electrical Trades Student Manual*, can be downloaded from the NIOSH Web site at www.cdc.gov/niosh/docs/2009-113/.

The nonprofit National Fire Protection Association (NFPA) has developed standard NFPA 70E, Standard for Electrical Safety in the Workplace. This was written to correlate with the National Electrical Code (NEC), which is applied to many local building codes and regulations.

35.3 CATEGORY RATINGS

Properly designed test meters should not cause a shock, fire, arcing, or explosion. They are also designed to reduce the potential damage that can result from operator error if the meter is connected improperly. Even so, this protection does have its limits! The wrong meter used for the wrong application is extremely dangerous! That is why there are four categories designated for low-voltage test equipment. Be aware that the term *low voltage* is deceiving, because for test meters this is considered to be 1,000 volts or less. Many HVACR technicians would consider any circuit of 480 volts or above to be high voltage.

There are a number of considerations taken into account for meter ratings. These include the safe distance to the power source the technician is working and transient voltage spikes. Motors, capacitors, and power-conversion equipment such as variable speed drives can be prime generators of spikes. Transients can occur on low-voltage power circuits and can reach peak values in the many thousands of volts.

Any time you are working with electricity, there is a possibility of an overvoltage situation occurring. We use surge protectors on our computers to protect them from overvoltage. A momentary surge or spike of voltage can be several times the normal circuit voltage. These surges, called transient voltages, can be caused by electrical storms, even miles away, or they can be caused when a major load is added or dropped from the system. Examples of changes in the load could be an auto accident where a utility pole was damaged, or a large piece of equipment starting or stopping.

Category numbers range from CAT I to CAT IV. A higher CAT number is used for higher voltages and energy transients. A test meter designed to a CAT III standard can resist much higher energy transients than one designed to CAT II standards (Figure 35-2). There are also voltage ratings within categories, such as a CAT III 1,000 V test meter has superior protection when compared to a CAT III 600 V test meter.

- **CAT I** is required for use on low-energy equipment such as protected electronic circuits and on high-voltage/low-energy sources from a high-winding resistance transformer. A typical example would be a photocopier machine.
- **CAT II** is required for single-phase receptacle connected loads such as appliances, portable tools, and other household-type loads. The outlet should be located at least 30 feet from a CAT III source.
- **CAT III** is required for distribution circuits such as three-phase bus and feeder circuits, load centers, and distribution panels. These test meters are also used for permanently installed loads such as three-phase motors, large commercial lighting systems, and heavy appliance outlets with short connections to the service entrance.

Figure 35-2 Category ratings of two voltage levels: CAT II 1000 V and CAT III 600 V.

- **CAT IV** is required for outside and service entrance use from the pole to the meter and the meter to the service panel. These test meters are also used for outside overhead and underground cable runs because they may be affected by lightning strikes.

Independent Testing Laboratories

A manufacturer may choose to self-certify a meter it produces without any independent verification. These meters may include a statement such as “designed to meet specification.” Be aware, however, that only test meters that are stamped with a symbol from a recognizable independent testing laboratory or approval agency can be considered to meet CAT requirements. Typical recognized agencies include the Underwriters Laboratories (UL), CSA, and TUV (Figure 35-3).

Meter Selection and Test Leads

Always choose a test meter rated for the highest category (CAT) you could be working in. A higher-category meter can be used for any lower-category applications. The voltage rating for the meter must also be considered. As an example, a CAT III 600 V meter has superior transient protection compared to a CAT II 1,000 V meter even though the voltage ratings may seem to indicate otherwise.

The test leads for the meter are just as important as the meter ratings. They should be certified to a category and voltage the same or higher than the meter (Figure 35-4). Alligator clips are handy in freeing up your hands from holding the test leads, which allows you more freedom to set the meter for the proper reading (Figure 35-5).

SAFETY TIP

Older test leads that you have used for many years may not be made with the insulation thickness needed for some of today's electrical systems. Try not to pinch leads in a panel door or kink them excessively in sharp bends. Test leads that are cracked, pinched, or excessively dirty should be replaced with new leads matching the rating of the tester.

35.4 METER TYPES: ANALOG AND DIGITAL

Digital meters are commonly used in the field today and have all but replaced analog-style meters. The following comparisons between them will highlight the advantages and disadvantages of both types.

Analog Meters

Analog meters are seldom used today because digital meters are superior in almost every way. Analog meters have a mechanical needle that swings across the dial to a point over a scale (Figure 35-6). The meter reading is taken by looking directly at the face of the meter dial and comparing the needle location to the appropriate scale. Some technicians prefer this type of display and consider it superior to a digital meter (Figure 35-7).

Digital meters display discrete number values, while analog meters provide a relative reading. An example is a digital watch compared to a watch with minute and second hands. Some people prefer the moving hands. Most

Figure 35-6 An analog multimeter has several scales, so you must know which range you are measuring and read the appropriate scale.

Figure 35-7 Analog electrical test meter.

cars use a speedometer needle for displaying relative speed rather than a digital number. The type of display then just becomes a matter of preference for the user. Some digital meters offer both types of display. They incorporate an analog sliding scale that appears across the digital meter face so that it is possible for the technician to have both the digital number and an analog reference (Figure 35-8).

Other than the needle display, analog meters offer no other true advantages. They are almost never auto-ranging. If too high a voltage is being tested for the scale setting, then the meter can be damaged. If you prefer to use an analog meter, there are three important characteristics that need to be considered:

- The most accurate reading is at the midpoint of the scale. So whenever the operator has a choice of scales, the one selected should place the pointer in the most favorable (central) position.
- Analog meters periodically need to be recalibrated. Most ohmmeters include some type of adjustment and instructions for calibration.

Figure 35-8 A digital meter displaying 7.89 megohms both as a numeric value and on a sliding scale.

- The small coil of wire that forms part of the meter movement is sensitive to excessive current. The meter may be made completely inoperable if subjected to excessive current. In using a meter with multiple scales to choose from, always use the higher scale first and move down to the scale required.

Digital Meters

Digital meters offer a number of advantages.

- They are direct reading, so there is no need to interpret the scale.
- Digital meters can be obtained that will give accurate readings to three decimal places.
- They have no moving parts and are less likely to fail or get out of calibration than analog meters, and they are more rugged.
- They often have automatic scaling features.

SERVICE TIP

Some digital meter displays are susceptible to water or humidity damage. It is important that these meters be kept as dry as possible so that they do not become damaged.

35.5 MULTIFUNCTION METERS (MULTIMETERS)

Having separate single-use meters was the only choice for years, until the introduction of the multifunction meter (multimeter). The different types of single-use meters would include the following:

- A voltmeter to measure electrical potential
- An ammeter to measure electrical current

- An ohmmeter to measure electrical resistance
- A megohm meter to measure very high electrical resistance (a megohm is the same as a mega ohm)
- A capacitor checker to measure capacitance, measured in microfarads (mfd)
- A wattmeter to measure electrical power

Today it is no longer necessary to carry all of these single-use meters. Multimeters will measure voltage, current, and resistance all with one instrument. Multimeters designed specifically for HVACR applications often provide additional measurements such as readings for capacitance, temperature, frequency, and power (Figure 35-9). Some have a diode function to determine the forward or reverse bias of a diode or if the diode is open or shorted. Many also provide features such as the ability to hold the value on the display screen (display hold) or record min/max averages. Many have auto-ranging capability, which is explained further in the next section.

(a)

(b)

Figure 35-9 (a) Measuring room temperature at 72°F with a multimeter and a K-type thermocouple; one more turn of the dial would allow for testing diodes; (b) K-type thermocouple.

TECH TIP

Digital meters are expensive and can be damaged if they receive rough treatment. To ensure that your instruments last as long as possible, they should be cleaned after each use and stored in their own individual case or pouch. It is also a good idea to carry your instruments in a separate bag away from your hand tools.

35.6 METER RANGE, RESOLUTION, AND ACCURACY

Range, resolution, and accuracy are three terms used to differentiate all meters. Understanding test instrument terminology will help you make the best selection of the instrument for your specific job requirements.

Range The range tells you how low and how high a reading the meter will provide for each function the meter can perform. Many meters today have an auto-ranging function (Figure 35-10). This means the meter sets the range to the best resolution for the input signal. Normally there is also a manual range mode that allows you to set the range yourself.

- Voltmeters should be able to read voltages from a fraction of a volt up to 600 V AC and DC.
- Ohmmeters should be able to read ohms from a fraction of an ohm up to 20,000 (20K) ohms.
- Mega ohm (megohm) meters should be able to read up to 40,000,000 (40M) ohms.
- Amp meters (ammeters) should be able to read AC amperage from 1 A up to 200 A and DC amps from 200 mA to 4,000 mA and from 0 to 20 μ A (microamps).
- Capacitance meters should be able to check from 1 μ F (microfarad) up to 200 μ F.

Resolution The resolution tells you what units of measure are used for each function. On a digital meter specification, it may be expressed as the number of digits or decimal points. This can range from three to four digits and one to three decimal places.

Figure 35-10 Auto-ranging multimeter.

Accuracy The accuracy is how close to the actual value the meter is going to read. These values are usually given as a percentage \pm (plus or minus) of the reading. Meters may vary from ± 0.5 percent up to ± 3 percent, depending on the function and scale.

35.7 TESTING A DE-ENERGIZED CIRCUIT

If you are testing to verify that there is no voltage present in a de-energized circuit before beginning work, there are three different test instruments that may be used. These are a noncontact proximity tester, an electrical tester, and a multimeter.

Testing electrical circuits is an important skill that each technician needs to develop. Although practice and experience are significant, a high degree of success is obtainable by following a proven procedure, such as the following:

1. Know the unit electrically. This means understanding the proper function of each control and the sequence of the control operation. It is as important to know what a meter does not measure as well as what it does.
2. Be able to read schematic wiring diagrams and have them available.
3. Be able to use the proper electrical test instruments. Know the instrument. Read instructions carefully before using.

CODE

NFPA Standard 70 E and NEC Article 110.16 define where and when personal protection equipment must be used. This equipment includes items such as eye protection, insulated hand tools, insulated gloves, and fire-resistant clothing.

Testing Procedures

Always try to work on de-energized circuits whenever possible, and follow the proper lockout/tagout procedures. Wear protective gear and stand on an insulated mat. Test the circuit in the following manner.

1. Make sure the circuit is off and properly locked out and tagged out.
2. Test the meter on a known voltage source.
3. Test the circuit that should be de-energized (off).
4. Test the meter again on a known source to ensure that you didn't damage your meter or blow a fuse and get a "0" volt reading accidentally in step 3.

Try to rest or hang the meter whenever possible rather than holding it in your hands. Alligator-clip test leads also allow you to keep your hands free by connecting one at a time and leaving them in place. Connect the ground test lead first and then the hot test lead last. Reverse this procedure to do the opposite for removal. Remove the hot test lead first and the ground test lead last. When connecting test leads, try to keep one hand in your pocket to lessen the chance of a closed circuit across your chest and through your heart.

Figure 35-11 Noncontact voltage detector lights up when voltage is present.

Low-Voltage Proximity or Noncontact Voltage Tester

This type of tester does not have test leads. The tester does not touch the conductor but is placed close (within proximity) to it. The tester will light up if voltage is present (Figure 35-11). These are good for a first test but should always be followed up with a direct-contact meter. This is because proximity tester readings can be inaccurate for a variety of reasons, such as when used inside a metal enclosure. Also, proximity readings will vary by distance and the strength of the voltage field and are therefore subject to some unreliability.

Electrical Testers

There are two general types of voltage testers: solenoid based and electronic. Both these types have test leads that must come in direct contact with the conductors. Solenoid-based testers that vibrate and light up are seldom used anymore (Figure 35-12). This is because there have been

Figure 35-12 Solenoid-based voltage testers such as the one shown are seldom used today due to safety concerns and accuracy at low voltages.

Figure 35-13 Multimeter with built-in noncontact voltage detector.

a number of safety issues involved with these, including that most are not fused. Another drawback is the sensitivity response of these testers. The circuit measured must have enough energy to move a spring-loaded slug. Therefore, low-voltage control circuits will not normally register on the indicator.

A better and more popular alternative is the electronic tester. These are fused for transient protection and are much more accurate. They have much higher input impedance so there is less input current required and the instrument remains cooler. Since they work with lower voltages, you are able to use the electronic test meter on a wider range of equipment. They are even designed to vibrate and light up to mimic the solenoid-based type.

Digital Multimeter

Multimeters can be considered the best instrument to test for voltage, but there are a few drawbacks as compared to the more simple voltage testers described previously. One drawback is operator error in turning the multimeter dial to the wrong function, such as amps instead of volts. This cannot happen on a proximity or electronic voltage tester. Another drawback for an older-type meter that is not auto-ranging is putting the meter into a range that is too high, which makes the voltage appear smaller than it really is. Some multimeters are now built with a voltage testing function that allows you to start with a noncontact proximity test and then move to a contact test, with the same instrument (Figure 35-13).

35.8 MEASURING VOLTAGE ON A LIVE CIRCUIT

It is not always possible to test only a completely de-energized circuit. Troubleshooting methods may often require that the circuit tested be "live." Testing for proper supply voltage is usually the first thing measured when troubleshooting a circuit. There are a number of safety considerations for testing a live circuit, such as location and setup.

CODE

OSHA and NFPA 70E, Standard for Electrical Safety in the Workplace, direct workers to de-energize all live parts to which an employee may be exposed, unless live conditions are required for troubleshooting.

Location and Setup

It is never safe to work on high-energy circuits without someone else present. Make sure the test meter is rated high enough for the reading you will be taking. Assess the location before you begin, and make sure the lighting is adequate. Find a location where you will place your meter so that you do not have to hold it. Magnetic hangers allow you to position the meter so that it can be clearly read without needing to be held. Determine if the leads will reach into the electrical cabinet without a need for extenders. Probe extenders keep your hands farther away from the conductors. Test probes with a minimum amount of exposed metal at the probe tips, such as .12 in (4 mm) metal-tip probes, will reduce the risk of accidentally shorting between two phases (Figure 35-14).

Attaching the Test Leads

Always use safe testing procedures as outlined in section 35.7. Whenever possible, attach the test leads to the conductors with the circuit de-energized. This can be done with alligator-clip-type test leads. Always connect the neutral test lead first and then the hot test lead last. The circuit may then be energized for the reading to be taken. Once the reading has been obtained, the circuit may once again be de-energized and the test leads removed by disconnecting the hot lead first and the grounded lead last.

Figure 35-14 (a) Long test lead tip with cover; (b) short test lead tip.

Figure 35-15 A voltmeter is connected parallel to the load.

If you need to probe the circuit, attach the black test lead with an alligator clip and use the red test lead to move from one conductor to the next. Keep one hand in your pocket and out of the panel so as not to offer a closed circuit path for the flow of electricity.

How to Measure Voltage

Voltmeters are connected in parallel with the load to read the voltage drop or potential difference. In testing a circuit for proper voltage, one lead goes on each side of the load, as shown in Figure 35-15. Many test meters today are auto-ranging, which means a specific range of voltage does not need to be selected. However, when using a test meter that is not auto-ranging, always start to measure voltage using the highest range on the meter—for example, 600 V. When the approximate voltage is read, the meter range can then be reduced to the proper range for greater reading accuracy—for example, start at 600 V then move down to 200 V. Also, using the meter to test a higher voltage than the range of the meter could cause burnout or otherwise damage the meter.

Read the instruction manual for the meter you are using. Some meters have function buttons in addition to the selector dial (Figure 35-16). On a dc circuit, the polarity of

Figure 35-16 In addition to a selector switch, some test meters have function buttons.

Figure 35-17 Open switch and a positive measured voltage.

the leads must be observed. Therefore, in DC circuits, verify the correct polarity of the probes that are used before connecting the meter to the circuit.

An example of a use for a voltmeter is to determine if a hidden switch is open or closed. This is very helpful in troubleshooting. If there is power in the circuit, and the leads of the voltmeter are placed on each side of the switch, a voltage reading indicates the switch is open (Figure 35-17), and a zero reading indicates the switch is closed (Figure 35-18) (if no other open switches are in the circuit).

Figure 35-18 Closed switch and no measured voltage.

Figure 35-19 Clamp-on ammeter that is also a multimeter.

35.9 AMMETERS

Amp meters (ammeters) are used to measure current flow through a circuit. There are two types of ammeters: clamp-on and inline. An advantage of the clamp-on meter is that it is not necessary to disconnect or make contact with any wires to obtain a reading; this is very convenient. The advantage of an inline meter is that it can provide very accurate current reading because all of the system current flows through the meter. Some of today's clamp-on ammeters are dual use and can serve both as inline (multimeters) and clamp-ons (Figure 35-19). Even so, there are often times when simultaneous readings of both voltage and amperage are required, and most common meters will not be able to read both at the same time. So for troubleshooting purposes, two meters work best, and many technicians will use both a multimeter and a clamp-on ammeter.

SERVICE TIP

For proper measurement, the jaws of a clamp ammeter are placed around only one conductor at a time. Some meters have flexible current probes in addition to solid jaws that can fit in tight cabinets and be squeezed between tightly packed wires or around a large conductor.

Clamp-On Ammeters

The clamp-on ammeter is one of the most useful of the electric meters for HVACR technicians. It is used to measure current flow through a single wire by enclosing the wire within the jaws of the instrument, as shown in Figure 35-20. Some clamp meters are capable of measuring both AC and DC current.

This instrument functions like a transformer. The primary coil is the test wire encircled by the jaws of the instrument. The secondary is a coil of wire within the instrument that is connected to the current-indicating mechanism. The current in the primary wire induces a flow of current in the

Figure 35-20 The most accurate amp measurement is when the wire passes through the center of the meter jaws.

secondary winding, measuring the current flow. The greater the current flow through the test wire, the greater the induced current and the greater the deflection of the needle reading on the scale.

Inline Ammeter

Inline instruments that only measure amperage are not commonly used. Instead, multimeters are the most common electrical measuring instrument for HVACR work because they are able to do so much more. Some multimeters have a removable clamp-on available as an accessory that may be used with the meter (Figure 35-21).

When using a multimeter as an inline meter, the proper location for its connections in a circuit is shown in Figure 35-22. Note that it is connected in series with the circuit being tested. In DC circuits, verify the correct polarity of the ammeter used before energizing the circuit. Never connect an ammeter across a load. It will be destroyed by line current, as there is no load to limit it!

Figure 35-21 Removable clamp-on accessory that can be connected to the multimeter for taking amperage readings.

Figure 35-22 An ammeter is connected in series with the load.

35.10 TEST METER FUSES

A somewhat common mistake for someone inexperienced in operating a test meter is to take a current measurement in line with the load and then next try to take a voltage measurement with the test leads remaining in that same position rather than placing them in parallel with the load. This effectively places a short across the voltage source. This could potentially destroy the meter. To prevent this, a fuse is located in series with the meter's test leads.

Not all fuses are the same. Even fuses of the same amperage and voltage ratings can be different from each other. Specially designed "high-energy" fuses have different circuit-interrupt characteristics. Some are filled with sand so at high temperatures the energy will melt the sand, turning it to glass to coat the element for increased protection against a meter explosion and meltdown. Using the wrong fuse or trying to jumper the fuse could result in an accident where a meter explosion could lead to serious burns to your arms, face, and clothing. Always refer to the test meter's manual, or check with the test meter manufacturer to ensure you have the correct fuse.

SAFETY TIP

A meter with a blown fuse should be put aside and not used again until there is a proper replacement fuse available. Never put in a fuse that is not correctly rated for the meter. If a wrong fuse is used, the metal element inside heats up very quickly, which can lead to a small explosion, resulting in the fuse enclosure bursting open and causing serious injury. *Never place a jumper wire around the fuse connections!*

35.11 TRUE RMS METERS

The term *RMS* is an abbreviation for root-mean square, a mathematical formula for calculating the electrical power passing through an alternating current circuit. True RMS

Figure 35-23 True RMS clamp-on ammeter measuring power factor.

meters have sensitive electronic circuits that can accurately measure voltage and amperage (Figure 35-23). Most meters called weighted average meters display the sensed voltage and amperage by averaging the readings over a short time period. However, some weighted-average meters provide RMS readings by applying a correction factor to the sensed voltage or amperage. These RMS meters may be more accurate than standard meters, but they are only averaging the true voltages and amperages.

Why Is True RMS Needed?

In the past, almost all of the equipment serviced by an HVACR technician had linear loads. Linear loads, like transformers, resistant heat strips, and so on, do not affect the power line sine wave (Figure 35-24a). Standard

meters work well on linear load circuits. However, more and more HVACR systems and other building loads are using semiconductors in their power and control circuits (Figure 35-24b).

The new semiconductor circuits are faster switchers and more reliable than the ones they are replacing. Their ability to energize and de-energize equipment so quickly causes changes in the power line’s smooth waveform. They disrupt this smooth waveform much like a speedboat’s wake disrupts the uniform smoothness on a lake. At times the speedboat’s wake can make the waves coming ashore larger, and other times they can be smaller. If you took the wave heights over time, you would not perceive any difference in wave power. But the occasional large boat wave comes crashing ashore with higher energy, which could cause damage.

True RMS meters can measure that momentary change in incoming line voltage. If there were only an occasional power peak, no long-term problem would occur. Unfortunately, this is not the case, because equipment such as variable-speed motors so common in HVACR equipment today constantly disrupts the wave power. They use power in very short pulses, which disrupts the

Figure 35-24a True RMS voltage plotted against non-RMS voltage.

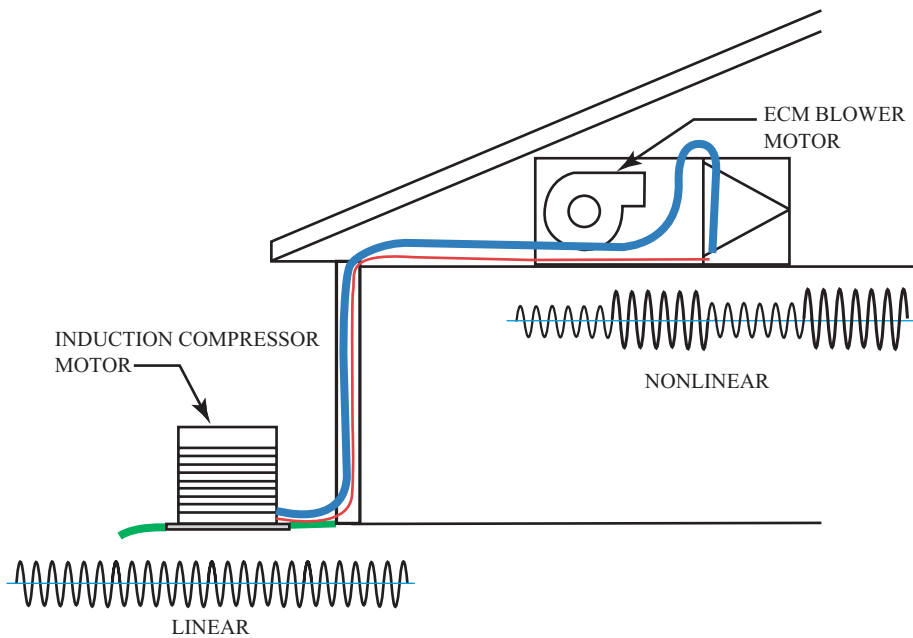

Figure 35-24b Weighted-average metering plotted against true RMS metering.

Figure 35-25 Linear vs. nonlinear power supply.

normally smooth linear line current making it rough and choppy (Figure 35-25).

The weighted averaging from non-RMS meters of voltage and amperage can result in readings that are 5 to 40 percent lower than the values that are actually being seen by the equipment. Small changes in operating voltages on induction motors can significantly affect current draw. Lower voltages cause higher amperage draws through the motor, which increases motor heat. A 20°F rise in motor temperature can cut the motor's life in half. Higher voltages can cause excessively high inrush currents at startup, which can also damage motors.

Using a true RMS meter is the only way to accurately measure voltage and amperage in nonlinear power applications.

35.12 OHMMETERS

Ohmmeters measure the electrical resistance and can be used to check a circuit for continuity. Multimeters will have this function and so will some clamp-on ammeters. *Continuity* means there is a complete electrical path. When the test leads are touching each other there is a complete electrical path (Figure 35-26). The meter is measuring the resistance of the wires of the test leads as 0.18 ohms. When the test leads are separated there is infinite resistance as indicated by the meter reading OL (Figure 35-27).

Not every circuit that tests OK for continuity is actually good. For example, a circuit that is grounded (shorted) to the unit case would show continuity to the case. All ohmmeters can check for continuity, but some have a special position that sounds a beep when there is continuity. The ohmmeter is different from an ammeter or a voltmeter in that it uses a battery as a power supply. The battery furnishes the current needed for resistance measurements.

**Figure 35-26** Test leads touching and the meter is reading 0.18 ohms.**Figure 35-27** Test leads separated and the meter is reading infinite resistance.

SERVICE TIP

The power to the circuit being tested must be turned off before testing a circuit for resistance. Further, if there are any capacitors in the circuit, they must be discharged before the meter is used. There can be only one source of power to the meter, and that must be be from the battery within the meter itself.

Using the ohmmeter to check for open circuits is called continuity testing. Figure 35-28 shows three diagrams representing the three possible responses that the meter can give.

- In Figure 35-28a, the meter is measuring the resistance through a pair of closed contacts in a circuit, and it registers zero. This indicates maximum current flow, or $0\ \Omega$ resistance. This is the measurement of a short circuit or a good set of closed contacts.
- In Figure 35-28b, the meter is measuring the resistance of a coil, which has a measurable resistance that is read on the meter.
- In Figure 35-28c, the meter is measuring the resistance of an open circuit, which is read on the meter as infinity. Infinity means that the resistance is so large that it cannot be measured. It means that at this point there is a lack of continuity or no current could flow.

Care must be taken to prevent errors in reading resistance when two or more circuits are connected in parallel, as shown in Figure 35-29. The meter in the illustration is actually reading the combined resistance of two parallel resistances, HTR1 and Blower. To read only one resistance, one side of the component being tested is disconnected, as shown in Figure 35-30.

Figure 35-28 (a) Closed contacts or a short will read as $0\ \Omega$; (b) a coil resistor will have a resistance reading between 0 and infinity; (c) an open contact or broken circuit will have an infinite (∞) resistance.

Figure 35-29 The ohm reading for Heater 1 would not be accurate because there are two paths, as shown in red.

Figure 35-30 The ohm reading would be accurate because the second path is now broken at the normally closed contacts.

Figure 35-31 NEVER use a multimeter to check an integrated circuit board chip.

SERVICE TIP

One caution needs to be followed: do not use an ohmmeter to test a solid state circuit unless the manufacturer specifically allows it. The internal battery voltage of the ohmmeter can damage an integrated circuit chip, as shown in Figure 35-31.

Megohmmeters (Meggers)

Some ohmmeters, often referred to as meggers (megohmmeters), must be able to read resistances of tens of millions of ohms (megohms) (Figure 35-32). Meggers are designed

Figure 35-32 Megohmmeter.

(a)

(b)

Figure 35-33 (a) Black test lead attached to motor housing; (b) red test lead attached to motor windings and black clip attached to motor housing.

to generate a high voltage across their test leads and therefore require more power as compared to regular ohmmeters. Meggers are used to test the resistance of insulation, particularly in electric motors.

For testing an electric motor, the power supply must first be disconnected and the motor isolated from the circuit. Then one test lead is attached to one phase of the motor while the other test lead is attached to ground, usually with an alligator clip (Figure 35-33). The ground connection is often the motor housing. When attaching the lead to ground, make sure to scrape any paint until bare metal is showing to ensure a good connection. A high megger reading would indicate that the motor winding and insulation are good (Figure 35-34). A low megger reading would indicate a shorted motor winding (Figure 35-35).

SAFETY TIP

Never touch the test leads when the megger is being used, because the megger generates a high voltage across them.

Figure 35-34 High megger reading indicates good insulation resistance.

35.13 CAPACITANCE METERS

Capacitance meters measure in microfarads (Figure 35-36). Most capacitors are within the range for nanofarad to microfarad. One microfarad is equal to one millionth of a farad. Before testing a high-voltage capacitor, always begin by properly discharging the capacitor first. The meter measures capacitance by charging the capacitor with a known current and measuring the resulting time of charging period. From this, the capacitance is then calculated by the meter.

The leads will have a residual capacitance. The known capacitance of the circuit shown in Figure 35-37 is 4 microfarads, as both 2-microfarad switches are in the closed position. The meter measures the circuit at 4.198 microfarads due to the capacitance of the meter leads as shown in Figure 35-38. Most meters will allow for the subtraction of the residual capacitance of the meter and leads. The meter must be connected for the proper polarity of the capacitor.

Figure 35-35 Low megger reading indicates shorted winding.

Figure 35-36 Capacitance meter.

Figure 35-38 The meter measures 4.198 microfarads instead of 4.0 due to the capacitance of the meter leads.

TECH TIP

An ohmmeter can be used as a quick check to test for a shorted or open capacitor. Analog meters have been commonly used for this because you can more easily see the meter movement. The test is performed by placing the two leads of the ohmmeter on each of the capacitor terminals for a few seconds and then swapping the leads. What this will do is charge the capacitor with the very low voltage used for ohm checking. In a functioning capacitor, when the leads are reversed, at first there will be a bump in the reading. Then, as the voltage bleeds off the capacitor, the needle will slowly swing back to the infinity (∞) position. If the capacitor is shorted out, there will be no bump and the reading will stay at zero. If there is no needle movement at all, then the capacitor is open.

35.14 WATTMETER

Power that is measured by simply multiplying the current by the voltage is called apparent power. However, this is not a true indication of power. To mathematically calculate power in watts using the measured volts and amps, it is necessary to know the power factor. Wattmeters incorporate the power factor to read true power (Figure 35-39). The meter makes the necessary calculations for power, in accordance with the power formula:

$$\text{watts} = \text{volts} \times \text{amps} \times \text{power factor}$$

Most wattmeters zero themselves when not in use and automatically select the proper range when used. They can be used to measure watts on single, split-phase, and three-phase power sources. Some multimeters and clamp-on ammeters have a power measurement function.

35.15 SPECIAL-PURPOSE METERS

There are many special-purpose meters designed for specific functions. Many digital meters have the capability to freeze and hold the reading or provide for a peak hold, a max hold, or a min/max hold. With some of these meters

Figure 35-37 4-microfarad circuit.

Figure 35-39 Digital wattmeter.

Figure 35-40 Digital power-quality analyzer with clamp-on accessory displaying circuit frequency.

you can see the starting current of a motor during start-up exactly as the circuit protector sees it (Figure 35-40). As the motor starts, the meter begins recording a large number of samples in as little as 100 milliseconds time and processes the samples to display the actual starting current. This type of meter can also be used to resolve intermittent breaker trips, helping to identify whether a nuisance trip is due to a faulty breaker.

Detachable Face

Detachable faces can be found on some multimeters and clamp-on ammeters. Some detachable displays can

be separated from the body of the meter by as much as 30 feet to allow you to take remote readings more safely. The detachable face is removed completely and not connected by wires. The connection between the detachable face and the body of the meter is a radio signal.

Data Logging

Data-logging instruments can be set up to record any number of data points from a few seconds to a month or more. These instruments are extremely valuable when dealing with customers' complaints like, "My unit runs all the time," "It's always hot in here," and so on. A data logger can prove or disprove these too common and often frustrating complaints. It can also help to solve troublesome intermittent problems that never seem to happen while you are working on the system.

Some data loggers display the logged data directly on the equipment display panel, while others can download the data to a computer for a comprehensive graphic analysis (Figure 35-41).

The newest line of data-logging instruments prompts the technician for information. They can connect the proper test device to the data logger, where it can collect the information directly from the device. With all of the data collected and the system equipment model number entered, the data logger will provide a comprehensive evaluation of the system's operation and its current level of efficiency. These data are automatically compared to the manufacturer's data, so the report can include specific recommendations if the system is not within the manufacturer's operating specifications.

UNIT 35—SUMMARY

A number of general principles should be observed in the use of meters, as follows:

- Always use the highest scale on the meter first, and then work down to the appropriate scale. This prevents damaging a meter by applying excessive power. An auto-ranging voltmeter will do this automatically.
- Always check the function of a meter before using it. Do not just assume a meter is working. If it is a battery-operated meter, the batteries may be run down. The meter could be damaged during transportation. Other things could happen to affect the readings.
- In using a clamp-on ammeter, be sure the jaws are around only one wire. If it is around two wires of the same circuit, there will be no reading at all as they will cancel each other out. Start at the high range and work down as described above.
- Always have an extra set of meter fuses on hand for replacement. Sometimes the proper fuses are difficult to obtain when you need them.
- Never use an ohmmeter in a circuit that is powered. An ohmmeter has its own power supply and can be destroyed by connecting to a live power source.
- If the meter uses batteries, have replacement batteries available. Older batteries can affect the readings the instrument provides. Colder batteries provide less voltage and current than warmer batteries. The condition of the batteries is not as important on digital meters, because they can compensate for low battery voltages automatically. Usually, digital meters will continue to operate until a LOW BATT icon is displayed.

Electrical Components

OBJECTIVES

After completing this unit, you will be able to:

1. determine the resistance value of a color-banded fixed resistor.
2. provide examples of where and how transformers are used.
3. identify paper and film, electrolytic, ceramic, and mica capacitors.
4. identify the different types of thermostats.
5. explain cut-in, cut-out, and differential on pressure switches.
6. test transformers, capacitors, contactors, and relays.
7. list the different types of fuses and overloads.
8. explain the difference between relay logic and solid-state logic.
9. describe how a silicon rectifier operates.

36.1 INTRODUCTION

Most HVACR service work deals with electrical problems. These problems can be caused by component failure, improper installation, or misuse. It is therefore important that HVACR technicians have a thorough and complete understanding of electrical components and wiring diagrams. Electrical circuits on different pieces of equipment will have similarities. Most circuits will have resistors, capacitors, relays, contactors, switches, and transformers. Understanding the function of each of these components will help you better understand how to troubleshoot a circuit. Electronic circuits with solid-state components are quickly replacing traditional electrical circuits, but many similar operating principles still apply. Therefore, this unit includes not only information on basic circuit components but also introduces the most common solid-state components.

36.2 RESISTORS

Resistors are found in many circuits (Figure 36-1). They are designed to allow for a measured resistance that can affect either voltage or current as calculated by using Ohm's law.

Figure 36-1 Resistors.

As an example, a resistor could be used in an electrical test meter to limit the current flow. Fixed resistors can be made from nickel wire wound on a ceramic tube and then covered with porcelain. Smaller fixed resistors are made from mixtures of powdered carbon and insulating materials molded into a round tubular shape (Figure 36-2). Variable resistors have a tightly wound coil of resistance wire made into a circular shape (Figure 36-3a,b). The resistance value is changed by turning an adjustment that moves the point of contact along the circular coil. Some variable resistors can be controlled by a small knob, while others are adjusted with a screwdriver (Figure 36-3c). Adjustable resistors are often used for electronic circuits.

Figure 36-3 (a) Resistance changes at different points along the resistance coil; (b) assortment of variable resistors; (c) a small, flat-tipped screwdriver would be require to turn the adjustment to change the resistance.

Resistor Color Bands

Markings on resistors can vary. Larger resistors have printed resistance values, while smaller resistors have color-coded bands. To determine the resistance of a color-coded resistor, start from the end opposite the silver or gold band. Use the color code chart from Figure 36-4 to determine the resistance values. The first two bands identify the first and second digits of the resistance value, and the third band indicates the number of zeroes. However, if the third band is silver, this will indicate a 0.01 multiplier. If the third band

is gold, this will indicate a 0.1 multiplier. The fourth band indicates tolerance. Silver indicates a ± 10 percent tolerance, and gold indicates a ± 5 percent tolerance. If there is no fourth band, the resistor tolerance is ± 20 percent.

Calculate the resistance of the resistor shown in Figure 36-5. The first band is orange, which is listed as number 3 on the chart. The second band is also orange, and the third band is red. The resistance therefore would be 3,300 ohms with a tolerance of 10 percent.

36.3 CAPACITORS

A capacitor will store energy when an electric charge is forced onto its plates from a power source. A capacitor will still retain this charge even after disconnection from the power source. However, it would be impractical to try to discharge the power from the capacitor into a different circuit, as you would do, for example, by placing charged batteries into your radio. Compared to a storage battery, the total amount of energy stored by a capacitor is relatively small. Also, the discharge rate of a capacitor is rapid, so the release of the stored energy only occurs during a short time interval. However, a mishandled capacitor will deliver a shock that can be severe and even fatal, especially for large capacitors charged to a high voltage.

Capacitor Types

Capacitors are rated for a maximum voltage by the manufacturer. This rating is usually expressed as the direct current working voltage (DCWV). Exceeding this voltage will shorten the life of the capacitor.

Capacitors can be used for a number of different applications. As an example, they can be used for tuning,

Figure 36-6 Disc ceramic capacitors.

filtering, energy storage, power factor correction, and motor starting. Capacitive filters are used to smooth pulsating DC and separate low-frequency AC from high-frequency AC. Capacitive tuners are used for tuning radios and television sets to the proper channel. Energy-storage capacitors are used in industrial applications such as capacitor discharge welding, where a large amount of stored energy is discharged rapidly. The leading current of a capacitor offsets the lagging current in an inductive load to allow for power factor correction. Many electric motors also utilize capacitors to produce a current phase shift in their windings.

Not all capacitors are made of the same materials. There are paper and film, electrolytic, ceramic, and mica capacitors. Disc ceramic capacitors are commonly found on electronic circuit boards and are typically 0.1 microfarads (mfd) or less (Figure 36-6). Mica capacitors are limited to even lower values than this (Figure 36-7).

For larger-capacitance requirements, paper and film capacitors are used (Figure 36-8). They are constructed using a rolled-foil technique. Once rolled, the capacitor may be dipped into a plastic insulating material. Capacitors of this type used for electronic circuits are rated at generally less than 1 mfd. However, they can also be designed for industrial applications to meet the requirements of several hundred microfarads. In this case, they would be housed in a metal container filled with special insulation oil.

Figure 36-7 Mica capacitor.

Figure 36-8 Rolled film and paper capacitors.

Figure 36-9 Electrolytic capacitors marked for polarity.

The type that provides for the most capacitance in relationship to their size and weight are electrolytic capacitors, which are commonly polarized. The polarity is marked on the body of the capacitor in some manner, as shown in Figure 36-9. Never reverse the polarity on this type of capacitor. This will lead to excessively high current, overheating, and possible explosion of the capacitor. A pop-out hole on some capacitors allows for the insulation to expand if the capacitor is overheated (Figure 36-10). If the hole is ruptured, the capacitor must be replaced.

Motor Capacitors

Capacitors for motors are classified as either starting capacitors or running capacitors. In replacing a capacitor, it is desirable to use an exact replacement. This means a capacitor with the same mfd rating and voltage limit rating. Do not interchange start and run capacitors (Figure 36-11). Start capacitors are high-capacity (50–700 mfd) electrolytic units that are intended for momentary use in starting

Figure 36-10 Motor-start capacitor with pop-out hole.

Figure 36-11 Assortment of both motor-start and motor-run capacitors.

Figure 36-12 159 to 191 mfd motor-start capacitor.

motors (Figure 36-12). They are normally encased in plastic. Run capacitors have much lower capacitance ratings (2–40 mfd) but are made for continuous-duty use. They are normally sealed in a metal can.

Motor-start capacitors are in series with the start switch and starting winding. This allows for a large phase shift to create a good starting torque. Since it is a starting capacitor only, it is not rated for continuous duty and is limited to about twenty starts per hour.

Motor-run capacitors are rated for continuous duty and are commonly used for permanent split-capacitor motors. The capacitor is matched to provide a 90° phase shift between current in the auxiliary and main motor windings at 80 to 100 percent of rated power. It stores and releases an electrical charge in the auxiliary winding to increase the current lag between it and the main winding. This is to balance the effective inductance and inductive reactance of the windings. The capacitor remains in the circuit the entire time the motor is running.

Some run capacitors have some sort of a mark, usually a red dot, as shown in Figure 36-13, to indicate the terminal that should be connected to the run terminal. With

Figure 36-13 The marked terminal on the run capacitor should be connected to the run terminal of the compressor.

this arrangement, an internal short circuit to the capacitor case will blow the system fuses without passing the current through the motor start winding.

36.4 TESTING CAPACITORS

The first operation in testing a capacitor is to discharge it. Do not discharge it by shorting out the terminals, as this can damage the capacitor. To avoid electrical shock, the technician should never place fingers across the terminals before properly discharging the capacitor.

The proper way to discharge a capacitor is to put it in a protective case and connect a 20,000 Ω , 2 W resistor across the terminals, as shown in Figure 36-14. Most start capacitors have a bleed resistor across the terminals. This makes it so the capacitor can be tested with the bleed resistor in place. Even so, it is good practice to make sure the charge has been bled off.

Capacitors can be roughly checked by using an ohmmeter. The ohmmeter used in testing capacitors should be able to read a high resistance and have at least an $R \times 100$ scale. To test the capacitor, disconnect it from the wiring and place the ohmmeter leads on the terminals, as shown in Figure 36-15.

If the capacitor is not shorted, the needle will make a rapid swing toward zero and slowly return to infinity. If the capacitor has an internal short, the needle will stay at zero, indicating that the instrument will not take the charge. What you are actually doing is attempting to charge the capacitor using the battery in the ohmmeter (be sure the battery in the ohmmeter is good). An open capacitor will read high with no dip and no recovery.

The use of a capacitor analyzer is highly recommended (Figure 36-16). This instrument will read the mfd rating and detect any breakdown in the dielectric underload conditions. It will detect any capacitors that have failed to hold

Figure 36-14 Using a bleed resistor on a start capacitor.

their ratings. It also is useful in measuring the rating of a capacitor that has an unreadable marking.

Most digital multimeters now have scales for testing capacitors. Set the meter to the capacitance test function and place the leads on the capacitor terminals (Figure 36-17).

36.5 TRANSFORMERS

HVACR equipment often requires more than one voltage. One or more transformers are often used to step down the line voltage to supply load or control requirements. Occasionally a stepup transformer may be used.

TECH TIP

There are several reasons that most HVACR equipment uses 24 V as the control voltage. First, under most state and local guidelines, an electrician's license is not required to install and service these low-voltage wires. Second, most codes do not require that these connections be made at electrical junction boxes. And third, under OSHA regulations, circuits that have less than 80 V fall under less stringent safety requirements.

Figure 36-15 Using an ohmmeter to test capacitors.

Figure 36-16 Capacitor test meter.

Figure 36-17 Testing a capacitor using the capacitor test function on a multimeter.

Transformer Design

Transformers are constructed using the induction characteristics of AC power. When current flows through a coil, a magnetic field is produced. When a second coil is placed in the field of the current-carrying coil (primary), electric current can be transferred to the second coil (secondary) (Figure 36-18). The process is made more efficient by wrapping the coils around a common metal core. The voltage transferred is directly in proportion to the ratio of the number of turns on the primary coil to the number of turns on the secondary coil. For example, a control transformer with a 240 V primary winding and a 24 V secondary winding has a 10:1 ratio: 10 turns of wire in the primary for every turn in the secondary.

More than one secondary coil can be used if additional voltages or circuits are required. Likewise, some transformers are made with more than one primary. These multiple windings can then be connected in series or parallel to change the voltage or current capability of the transformer.

Center-tapped transformers allow for a small change in the windings voltage rating by changing taps. Typical residential voltage is 120 V, but this can vary. A center-

Figure 36-18 Primary and secondary voltages of a step-down transformer.

Figure 36-19 The primary voltage for this transformer depends upon the tap used.

Figure 36-20 Variable autotransformer.

tapped transformer could be connected to meet varying requirements. As an example, a transformer that has multiple primary taps could be connected for 120 V, 208 V, or 240 V, depending on the tap used (Figure 36-19). Variable autotransformers also allow for changing the voltage output (Figure 36-20).

Three-phase transformers are generally used for three-phase power. However, a single-phase transformer for each leg (three single-phase transformers) would produce the same results.

Transformer Application

There are many different types of transformers for many different applications. Large power transformers are designed to operate at electric utility voltages from 115 V to several thousand volts (Figure 36-21). A common use for some smaller transformers is to provide low-voltage ac to

Figure 36-21 Typical line voltage power transformer.

rectifiers for conversion to dc. These would be called rectifier transformers. Air-conditioning systems use low-voltage transformers to provide 24 V ac to control circuits to operate relays and solenoids. These step down the voltage from line voltage to 24 V and are referred to as control transformers (Figure 36-22).

Equipment that is very sensitive to voltage changes use constant voltage transformers. Electronic devices may use the metal chassis where components are mounted as a common conductor. If you touch the metal chassis accidentally while there is power, you will receive a shock. Isolation transformers are used to break the circuit and protect the technician.

Figure 36-22 Control voltage transformer.

Figure 36-23 Stray eddy current flow through the transformer core is reduced by the oxide surface treatment of the laminations.

Transformer Construction

Transformers will heat up during operation. This production of heat is inefficient. Transformer cores are made of thin sheet-metal strips in the form of a laminate. There are a number of advantages to using thin sheet-metal strips. It is far easier to manufacture thin sheets because they can be stamped, where the thicker material would have to be cut. Also, the voltage induced in the core will cause current, called eddy current, to circulate (Figure 36-23). Each metal strip is insulated with a thin layer of oxide, which resists the flow of eddy currents (Figure 36-24). This reduces unwanted current circulation through the core and excessive heating of the transformer.

Transformer Operation

The voltage ratings for transformers are specified by the manufacturer for both primary and secondary windings. A primary winding operating at above its rated voltage will overheat. Current ratings are often only provided for the secondary winding. This is because the primary winding current capacity cannot be exceeded before the secondary winding. When the current rating of the secondary is exceeded, the voltage output drops below the secondary voltage rating. This causes the transformer to heat up, shortening its life.

Transformers are commonly rated by volt-ampere ratings, abbreviated VA (Figure 36-25). The VA rating is literally the voltage multiplied by the current, amps. VA ratings are used because they apply to any load, whether resistive, reactive, or combination (impedance). Inductive loads convert electricity to magnetism. The coils of relays, contactors, and solenoids are all examples of inductive loads. The current and voltage get out of phase in inductive loads, so the wattage is actually less than the volts times the amps. VA ratings show the combined effect of volts and amps on the transformer regardless of the type of load on the transformer.

Note that the amp draw of the secondary is much higher than the amp draw of the primary. Take, for example, a 48 VA transformer with a 120 V primary and a 24 V secondary. The primary current = $48 \text{ VA} / 120 \text{ V} = 0.4 \text{ amps}$. The secondary current equals $48 \text{ VA} / 24 \text{ V} = 2.0 \text{ amps}$. Note that this example ignores the heat given off. This is why the

Figure 36-24 Laminations are clearly visible on most transformers.

Figure 36-25 Industrial control transformer with a .050 KVA rating.

secondary winding is made from heavier-gauge wire than the primary winding.

Efficiencies for transformers are higher when they operate more fully loaded. The primary winding current is mostly inductive, making it nearly as much as 90° out of phase with the voltage. The mostly resistive secondary winding current will offset this at higher transformer loads so that the total current is more in phase with the voltage and therefore more efficient. When operating without a load, all the current the transformer draws is waste. When operating fully loaded, most of the current is going to the load.

36.6 FUSES

Where the power comes into the building, it enters a service entrance panel for distribution to the various electrical loads (Figure 36-26). Each electrical circuit that comes from this panel is electrically protected by either a fuse or a circuit breaker.

A sample fuse and two commonly used fuse symbols are shown in Figure 36-27. A fuse is a special electrical conductor

Figure 36-26 Residential service entrance panel with the access cover open to provide access to the circuit breaker switches.

Figure 36-27 A cartridge fuse and its common symbols.

that is placed in series with a load and melts when excessive current flows through it, opening the circuit. Fuses are available in different types and sizes so that they can be selected to match the requirements of specific loads (Figure 36-28). If they are too small, they melt before they should. If they are too large, they do not offer the proper protection. Their selection follows the rules set forth in the electrical code or in the specifications accompanying the load.

Figure 36-28 Fuses located in an air-conditioning console.

Figure 36-29 250 volt fuses: 30 amp on left and 60 amp on right.

Cartridge fuses are the most common in HVACR. They are rated by voltage, current, and maximum instantaneous current. All their values should be matched when replacing a fuse. Fuses are grouped by physical size. Up to 30 amps is one physical size; over 30 amps and up to 60 amps is a larger size (Figure 36-29). Fuses are also rated for voltage. Fuses designed for 600 volts are much larger than fuses designed for 250 volts (Figure 36-30). Fuses must withstand incredibly high amounts of energy when they are subjected to a direct short. Not all fuses have the same ability to withstand the same levels of energy. Less expensive fuses have lower instantaneous current ratings. The two fuses in Figure 36-31 are both 600 V, 30 A fuses, but the one on the right has a rating of only 50,000 amps while the one on the left can withstand 200,000 amps. The fuse on the right would literally explode if it were subjected to 200,000 amps.

Because motors draw four to five times their normal operating current when they start, standard fuses often blow during normal motor operation. Where fuses are used to protect motors in the circuit, a special type of fuse is used called a dual-element time-delay fuse. This type of fuse has a built-in delayed action that will tolerate momentary heavy starting current on motor power-up but functions the rest of the time to protect the motor against excessive running current.

Figure 36-30 Both fuses are rated at 30 amps. The larger one is rated at 600 V, while the smaller one is rated at 250 V.

Figure 36-31 Even though both fuses are 600 V 30 amp fuses, the fuse on the left has an IR rating of 200,000 amps, while the fuse on the right has an IR rating of 50,000 amps.

CODE TIP

UL requires a dual-element time-delay fuse to withstand 500 percent of the fuse amp rating for 10 seconds. Dual-element fuses achieve the time delay by using two separate elements: one for short circuit protection and another for overload protection.

36.7 CIRCUIT BREAKERS

All residences have some type of electrical panel, where the electrical service enters the building and is distributed to the circuits in the building. Each circuit has some type of protective device to automatically disconnect the power in case the circuit is overloaded. This protection can either be a fuse as described above or a circuit breaker. Note the symbols used to represent a circuit breaker in an electrical wiring diagram (Figure 36-32). The advantage of a circuit

Figure 36-32 A circuit breaker and its common symbol.

Figure 36-33 Small power switch.

breaker over a fuse is that it can be manually reset at the electrical service panel after an overload, rather than replaced. Also, the circuit can be manually opened in case there is a need to perform service on the circuit. Three types of breakers are available: standard, GFCI, and AFCI. Standard breakers protect circuits against too much current, but they cannot detect if current is going where it should not go. In addition to protecting against too much current, ground fault circuit interrupter (GFCI) breakers protect against current that flows somewhere outside of the normal current path. An arc fault circuit interrupter (AFCI) protects against electrical arcs.

36.8 SWITCHES

Switches can come in all shapes and sizes (Figure 36-33). Often they are normally open and when the switch position is changed from OFF to ON, the switch contacts will close and energize a circuit, the same as when you turn on a light. Switches can also be designed to be normally closed, which de-energizes the circuit when the contacts open (Figure 36-34). An example would be a stop switch to shut down a motor. Proximity switches often limit motion and are often operated by the movement of a mechanical device (Figure 36-35). An example would be a switch that stops the motor used for opening air inlet dampers once they have reached a full open position.

General-duty switches are designed for use in residential and commercial applications. These are used for relatively

Figure 36-34 The black switch is pushed to start (normally open), while the red switch is pushed to stop (normally closed).

Figure 36-35 This proximity switch is operated by some controlled mechanical movement.

Figure 36-36 Residential safety switch.

light-load applications such as general air-conditioning and appliance loads. There are several different kinds of these switches, and some will have fuses while some others will not. A typical residential safety switch is shown in Figure 36-36. Switches are rated by the voltage and current they can safely switch (Figure 36-37). Operating a switch on a higher voltage or heavier current than its rating is dangerous.

Air-conditioning systems use many switches that open and close based on a particular condition. Examples include thermostats that open and close based on changes in temperature, humidistats that open and close based on changes

Figure 36-37 This switch is rated for 120 V and 15 amps.

in humidity, and pressure switches that open and close based on changes in pressure. These can be divided into two general categories: line voltage and low voltage. Line-voltage switches are referred to as line duty, while low-voltage switches are referred to as pilot duty.

36.9 LOW-VOLTAGE THERMOSTATS

A thermostat is a switch that is operated based on changes in temperature. Low-voltage thermostats operate on 24 volts and normally do not switch more than 2 amps. Low-voltage thermostats typically control several system functions. They operate like a bunch of switches, each one with a specific function. However, instead of operating the system by manually flipping all the appropriate switches, the thermostat does it automatically for you.

Low-voltage thermostats have two manual switches: a system switch and a fan switch. The system switch controls the operating mode: Off, Cooling, Heating (Figure 36-38). The fan switch controls cycling of the fan. In the ON position, the fan operates all the time, regardless of the thermostat setting. In the AUTO position, the fan cycles with the system (see Figure 36-38).

For many years, thermostats were electromechanical, using bimetal coils to move mercury bulb switches (Figure 36-39). The bimetal element is composed of two different metals bonded together. As the temperature surrounding the element changes, the metals will expand or contract. Since

Figure 36-38 The system switch and fan switch on a typical low-voltage thermostat.

Figure 36-39 Older bimetal element and mercury bulb thermostat.

Figure 36-40 Thermistor sensor used in electronic thermostat.

the metals have different coefficients of expansion, one will expand or contract faster than the other. This creates movement in the bimetal such as twisting or turning. A mercury bulb attached to the bimetal acts as a switch. The contacts are enclosed in an airtight glass bulb containing a small amount of mercury. When the bimetal tilts the bulb, mercury in the bulb will roll to one end and complete the electrical circuit.

Newer low-voltage thermostats are now digital, using thermistors to sense the temperature and logic to control the operation of electronic switches or relays inside the thermostat (Figure 36-40). Electronic digital thermostats are considerably more accurate than older electromechanical thermostats. They will control the temperature within 1°F, while the bimetal thermostat controls to an accuracy of about 3°F. Digital thermostats require voltage to operate their logic boards. Some require both sides of the 24 V control power to operate, others steal power from the circuits they are controlling, and many use batteries. Some may work with either 24 volts or batteries.

Many thermostats are now touchscreen units with no actual switches at all (Figure 36-41). However, they still retain the same basic functions of the old electromechanical thermostats. They still have a virtual system switch that selects the system operating mode and a virtual fan switch to select continuous operation or automatic cycling (Figure 36-42).

System operation is controlled by energizing terminals that energize different parts of the unit. Because the operation of furnaces and heat pumps are quite different, thermostats are normally designed to control furnaces and air conditioners, or they are designed to control heat pumps. However, many digital thermostats now will work with furnaces, heat pumps, or a combination of both depending upon the thermostat configuration. The specific terminals that are energized in heating or cooling operation and the way they cycle are determined by the thermostat configuration. Figure 36-43 shows a configuration screen from a touchscreen thermostat that can be configured for many types of systems.

Figure 36-41 Touchscreen thermostats have no physical switches.

Figure 36-42 Virtual fan switch and system switch on a touchscreen thermostat.

Staging thermostats allow more than one stage of heating or cooling. In general, operating just the amount of heating or cooling necessary saves energy and money. The unit can use less energy by operating on first stage at a lower capacity most of the time. Heat pump systems typically use the second stage of heat to control auxiliary heat. If the first stage cannot meet the demand, a second stage is energized. Many two-stage furnaces are now available with low-fire and high-fire operation. Air conditioners and heat pumps are also commonly available with two capacity compressors. Staging thermostats are required for all these applications. Often, a configurable staging thermostat is used so that the thermostat function can match the system needs. More details on low-voltage thermostats and their circuits can be found in Unit 39, Control Systems.

Electronic programmable thermostats can be set for different temperatures for time periods throughout the week.

Figure 36-43 Configuration setup screen on a touchscreen thermostat.

Figure 36-44 The current ratings on a line voltage thermostat.

These settings will take effect automatically. Most programmable thermostats divide the day into four periods: waking, leaving for work, arriving home, and going to bed. They allow you to set a different temperature for each of these four periods. A heating thermostat with night (or unoccupied) setback will automatically reduce the control set point during preset periods when lower than normal temperatures are acceptable. A cooling thermostat will have setup to raise the set point during scheduled hours. The intent of setup and setback is to reduce cooling and heating energy usage. Three levels of programmable thermostats are available: one program, separate weekday and weekend programs, or full 7-day programmability. The least expensive run the same program every day. The weekday-weekend thermostats have one program for the week and another for the weekend. The 7-day programmable allows a different program for every day of the week.

36.10 LINE VOLTAGE THERMOSTATS

Line voltage thermostats are designed to switch circuits that operate on the line voltage supplied to the unit, such as 120 V or 240 V. The switching action is described as open on rise or close on rise. An open on rise thermostat is used to control heating, while a close on rise switch is used to control cooling. They typically can handle 15 to 25 amps at 120 V (Figure 36-44). All line voltage thermostats have a switch, a sensing mechanism, and a mechanical linkage to allow the sensing mechanism to operate the switch (Figure 36-45).

Figure 36-45 The switch, sensing bulb, and bellows on a line voltage thermostat.

Figure 36-46 Remote bulb thermostat.

The most common temperature-sensing mechanisms are charged bulbs and capillary tubes.

Charged bulbs contain a volatile fluid that increases in pressure when its temperature is increased. This pressure pushes on a bellows that operates the switch. An adjustable spring pushes against the bellows, allowing temperature adjustment. Figure 36-46 shows a charged bulb thermostat. This thermostat is sometimes referred to as a remote bulb thermostat. The controlling bulb can be placed in a location away from the body of the thermostat. For example, the bulb for a commercial refrigeration cooler can be placed inside the cooler with the capillary tube run through the wall to the thermostat located outside the room. Thermostat adjustments can be made without entering the refrigerated room.

Capillary-tube thermostats use a diaphragm mechanism instead of a bellows (Figure 36-47). In this control, the diaphragm is completely filled with liquid. The liquid expands and contracts with a change in temperature. The movement of the diaphragm is very slight, but the pressure that can be exerted is tremendous. Because the coefficient of expansion of liquid is small, relatively large-volume bulbs

Figure 36-47 Capillary-tube thermostat.

are used on the control. This results in sufficient diaphragm movement and also ensures positive control from the bulb.

36.11 HUMIDISTATS

Humidistats control the operation of their switch based on changes in humidity. Hygroscopic elements are used on these controls, including human hair (Figure 36-48). As the moisture content of the air increases and the humidity rises, the hair expands and allows the electrical contacts to close (or open). As the humidity level decreases and the hair begins to dry, it contracts and once again activates the electrical contacts. This type of control is susceptible to dirt and dust in the air.

A more common form of humidistat uses a nylon element instead of human hair (Figure 36-49). The nylon is bonded to a light metal in the shape of a coil spring. The expanding and contracting of the nylon creates the same effect as that found in the spiral bimetallic strip used in thermostats. Another type uses a thin, treated nylon ribbon as a sensor.

An electronic circuit board can have hygroscopic properties, and lithium salt is used for this purpose. Another arrangement uses carbon particles embedded in a hygroscopic material. In both cases, the sensing element acts as a thermistor. Changes in the humidity affect the resistance of the material and alter the current in the electronic circuit.

Figure 36-48 Humidistat with hair for the sensing element.

Figure 36-49 Humidistat with a nylon sensing element.

36.12 PRESSURE SWITCHES

Similar to a line voltage thermostat, a pressure switch uses a diaphragm or bellows to operate a switch. The difference is that the pressure operating the pressure switch comes directly from the refrigeration system. The pressure switch is either attached directly to the system, as in Figure 36-50, or it has a capillary tube that connects the pressure switch to the system, as in Figure 36-51.

The switching action of a pressure switch is described as either close on rise or open on rise. A high-pressure switch whose purpose is to shut the unit off when the high-side pressure exceeds a safe level uses an open-on-rise switching action. A low-pressure switch whose purpose is to shut

Figure 36-50 Pressure switch attached directly to the system.

Figure 36-51 Pressure switch connected to the system with a capillary tube.

off the system when the low-side pressure drops below a safe level uses a close-on-rise switching action. Because many commercial refrigeration systems use both a close-on-rise low-pressure safety switch and an open-on-rise high-pressure safety switch, dual-pressure switches combine the two switches into one mechanism (Figure 36-52).

(a)

(b)

Figure 36-52 (a) Combination high- and low-pressure switch; (b) the high- and low-pressure sides of this control are separated inside the switch.

These have two pressure bellows controlling the same set of electrical contacts. The contacts will open if the high-side pressure exceeds the setting of the high-pressure switch or the low-side pressure falls below the setting of the low-pressure switch.

The pressure at which a switch closes and the pressure at which it opens cannot be the same pressure. There must be a difference between the two for the switch to work. The point where the switch closes is called cut-in, and the point where the switch opens is called cut-out. The difference between the two is differential.

Adjustable pressure switches allow adjustments to the operating point and the differential. Adjustable pressure switches are often used in commercial refrigeration. Close-on-rise switches have an adjustment for the cut-in and the differential. The cut-out is set by setting the cut-in and differential. For example, a switch with a cut-in of 250 psig and a differential of 50 psi would have a cut-out of 200 psig (Figure 36-53). Open-on-rise switches used for safety controls typically only have an adjustment for the cut-out. The differential is pre-set and not adjustable.

Air-conditioning systems typically use small, fixed pressure switches connected directly to the system (Figure 36-54).

These switches are not adjustable and are manufactured to open and close at a pre-set pressure. These small, fixed pressure switches are normally pilot-duty switches, rated only for low-voltage, low-current applications. Typical applications include high-pressure and low-pressure safety cut-out

Figure 36-53 The cut-out on this low-pressure switch is 200 psig: 250 psig cut-in and 50 psi differential.

switches. They are usually wired in series with the contactor coil. When they open, they break the circuit to the contactor coil and the contactor opens to turn off the compressor.

36.13 FLOW SWITCHES

Flow switches open or close based on the movement of fluid. Note that both air and water are fluids. The sail switch, shown in Figure 36-55, is a protective device to prevent the operation of a unit when there is inadequate fluid flow. In an air system, the sail switch is placed in the duct to sense the flow of air. Unless there is an adequate supply of air over the coil, the unit is either not started or shut down. Switches of this type can also be placed in a waterline feed of a water-cooled condenser. If there is an inadequate supply of water, or no water, the unit is prevented from running.

Figure 36-55 (a) Sail switch to detect airflow; (b) electronic flow switch.

Figure 36-56 Cutaway of a solenoid valve.

36.14 SOLENOID COILS

A solenoid coil is a doughnut-shaped coil of wire that produces a strong magnetic field when energized. Solenoid coils typically have steel plungers that are attracted to the coil when it is energized. The movement of the plunger can be used to control many HVACR electrical devices including solenoid valves, gas valves, relays, and contactors.

Figure 36-56 shows a cutaway of a solenoid valve. A solenoid valve is an electrically operated valve that controls the flow of a fluid by opening or closing when the solenoid coil is energized. They may be either normally open or normally closed. When the coil is energized, the valve will change position. Normally open valves will close; normally closed valves will open.

36.15 RELAYS

An automatic switch requires some method for opening and closing. This is often accomplished through the use of a relay (Figure 36-57). A relay is an electrically operated switch that uses an electromagnet to open or close a set

Figure 36-58 The visible coil of fine wire is the part of the electromagnet arrangement of this relay.

of electrical contacts (Figure 36-58). Normally only a small amount of current is required to energize the electromagnet. This allows for a device with a high current rating, such as an electric heater, to be operated by a control relay operated by a low-current signal. The control wires can be much smaller and separate from the large main supply lines required for the main load.

Relays can be designed for normally open switches or normally closed switches. The normal position of the switch is always the position of the switch when the relay coil is de-energized. Figure 36-59a shows a normally closed set of contacts with the relay coil de-energized. A spring is used to hold the contacts together. When the coil is energized (supplied with current) (Figure 36-59b), a magnetic field is set up that attracts the lower contact toward the coil. This will separate the two contacts and open the circuit. As long as the current flows through the coil, the relay is energized, and the switch will remain open. With a normally open

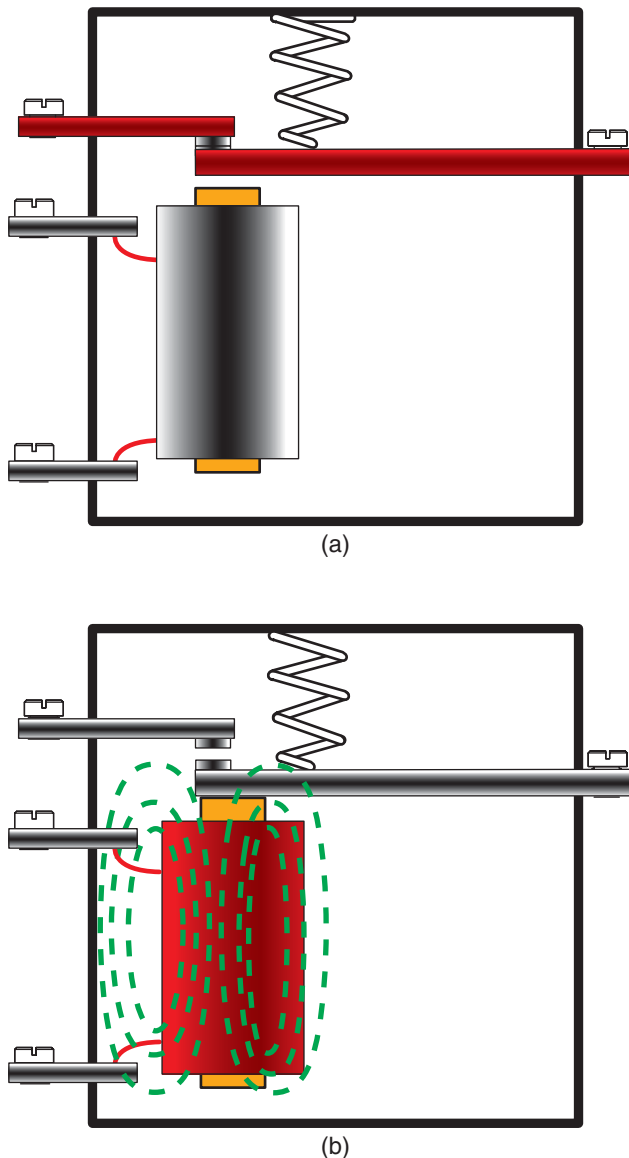

Figure 36-59 (a) The coil is de-energized and the contacts are held closed by spring force; (b) the coil is energized and the contacts are opened by the magnetic attraction of the coil.

set of contacts, the spring holds the contacts open. When the coil is energized, the magnetic field pulls the contacts together.

Relay coils are available in all common voltages, including 24 V, 120 V, and 230 V. There is no electrical connection between the coil and the contacts. The contacts are separate electrical devices and have their own rating. The contacts are rated for both voltage and amperage. It is common for the contacts to switch higher voltage than the coil voltage.

36.16 TESTING RELAYS

The relay coil can be tested by checking its resistance. The coil should be disconnected from the circuit to ensure that you are only checking the coil. This can be done by disconnecting the wires from the coil. Relay coils should have a measureable resistance: not open and not shorted. A meter reading of infinite Ω (OL on most digital meters) indicates that the coil is open. A reading of 0 Ω indicates that the coil is shorted. The coil resistance will vary depending upon the design of the relay and its operating voltage. The contacts should ohm as either open or shorted because they are a switch. With the coil de-energized, the normally open contacts should read infinite Ω (OL) and the normally closed contacts should read 0 Ω . When the coil is energized, the readings reverse: the normally open contacts should read 0 Ω and the normally closed contacts should read infinite Ω (OL). They should never have a measurable resistance.

36.17 CONTACTORS AND STARTERS

Relays, contactors, and starters all have contacts that open and close to complete or disconnect a circuit (Figure 36-60). Contacts for control relays are often very small (Figure 36-61). This is because they do not need to be connected to the load current, since they are only relaying the signal. Typically, relay contacts are rated for 15 amps or less.

Contactors that are connected in the load circuit will need to be larger (Figure 36-62). The operation of a contactor is shown in Figure 36-63. There may be one or more sets of contacts located on the armature. Contactor poles are the number of contact sets. A single-pole contactor has one set of contacts, a two-pole has two sets, and a three-pole has three sets. The armature moves up and down in

Figure 36-60 (a) Fan relay; (b) three-phase contactor; (c) single-pole contactor; (d) motor starter; (e) large-amperage systems may use multiple contactors all wired together.

the holding coil. When the coil is energized the armature moves and closes the contacts. The contacts are considered normally open since they are open when no current is applied to the coil. Contactors may also be designed to have normally closed contacts that are closed when the coil is de-energized.

The contacts are rated by the voltage and current they can switch. There are normally three current ratings: resistive, FLA, and LRA (Figure 36-64). The resistive rating is the

(a)

(b)

amount of current the contacts can switch for a resistive device such as an electric strip heater. The resistive rating is higher than the FLA (full load amps) rating because resistive loads do not have a high starting current. FLA is the current rating for motors. A motor's FLA current is the amount it draws when doing the full amount of work it was designed to do. A contactor's FLA rating is lower than its resistive rating because of the high starting current of motors. The LRA rating stands for locked rotor amps. A motor's LRA is the amount of current the motor draws if it is energized while its rotor is not moving. This current is very high, typically four to five times as high as the FLA operating current.

Figure 36-64 The current ratings on a contactor.

SERVICE TIP

The contact surface in relays and contactors is coated with a special alloy of very conductive material. This coating is very thin but effective in preventing the contacts from becoming quickly damaged from the momentary arc as they open and close. This arc would normally cause the contacts to weld themselves together. Over time this protective coating will wear away and the contactors may eventually begin to occasionally stick. When sticking occurs, the contactor or contactor tips must be replaced. They cannot be reconditioned in the field with point files. The substructure of the contact is a thermally conductive material that helps carry the heat away from the coating. It is not resistant to arcing and welding itself together. A reconditioned contact surface will stick again very quickly. Do yourself and your customer a favor and replace sticking contacts whenever they are found.

Starters for motors need to be even larger. A motor starter or magnetic starter is essentially a contactor with built-in overload protection. The current passing through the contacts also passes through overloads. If any of the overloads open, they break the circuit to the starter coil, shutting it down. The control voltage is used to operate the holding coil on a starter as well as for many other control functions. Motor starters work on the same magnetic coil principles as relays and contactors, but the actual contact size will be greater. The contacts should snap open and close with spring assist to reduce arcing across the contacts. A magnetic starter is shown in Figure 36-65.

Motor starts are often used with three-phase motors. Since three-phase motors have three circuits, opening any one leg of power still leaves an energized circuit. The overload in a magnetic starter protects the motor by breaking the circuit to the starter coil, which then opens the contacts, de-energizing all three circuits.

Figure 36-65 Magnetic motor starter.

Figure 36-66 Manual reset overload.

36.18 CURRENT/TEMPERATURE SAFETY COMPONENTS

Electrical overloads provide for protection against excessive current. Overloads can be line duty or pilot duty. Line-duty overloads break the power to the device they are protecting. Pilot-duty overloads operate like relays. They have a separate coil and contacts. Once they have tripped, some overloads reset themselves automatically after cooling down. These are called automatic reset overloads. Others use a mechanical design that requires a button to be pushed to reset it (Figure 36-66).

Line-Duty Overloads

Thermal bimetal overloads used with electric heaters are a good example of a line-duty overload (Figure 36-67). They open to break the circuit to the heater if the strip heater overheats.

The bimetal overloads are often used on small hermetic compressors (Figure 36-68). They have a small heater and a bimetal that controls a set of contacts. When the current passing through the heater exceeds the overload rating, the heater will cause the bimetal to warp, opening up the contacts and breaking the circuit. Many current overload

Figure 36-67 Thermal overload used to protect electric strip heaters from overheating.

On short circuits, or extreme overloads, the movable core is not a factor because the strength of the magnetic field of the coil is sufficient to move the armature without waiting for the core to move. The time-delay characteristics are built into the overload and are a function of the core design and fluid selection.

36.19 ELECTRONICS AND LOGIC CIRCUITS

Electrical circuits can have any number of input devices. Some examples are pushbuttons, mechanical limit switches, pressure switches, and photo cells. This input is then transmitted in a logical fashion to an actuating device. These could be relays, contactors, motor starters, solenoids, or some component that will start a series of event to satisfy the initial input.

Relay Logic

Many systems have been designed to use relay logic. These circuits will make decisions based upon the initial input. Take, for example, that the input is a call for heat by the thermostat. This input signals for contacts to close, which will energize a relay, and this begins a sequence of events to start the furnace. If a flame is detected, the furnace continues to run. If not, the furnace shuts down. This could be seen as an OR function. Stay running OR shutdown.

From this example, it can be seen that with relay logic, relay coils are designed to control other relay coils. Two contacts wired in series would be considered an AND function. First one contact closes AND the second contact closes to energize the load. Contacts in parallel will produce an OR function. Contact 1 OR contact 2 will close.

Relay logic is quickly becoming replaced by electronic systems. One reason is that mechanical switches never truly make a good, clean closing contact. The points tend to bounce against each other several times before fully closing. Sometimes this causes minor sparking. Relays like this cannot be used in an explosive environment unless they are enclosed in an airtight container. Sometimes capacitive switch filters are used to help smooth out this bounce.

Contacts also wear out over time as they continually open and close. They are exposed to any chemicals or dust in the air, and mechanical linkages can eventually stick and the contacts become pitted. In comparison to electronic solid-state logic, relays are slow and heavy.

Solid-State Logic

Unlike relay logic, solid-state components have no moving parts (Figure 36-71). They are sealed from the atmosphere. They take up less space because most of the components are attached to a compact circuit board (Figure 36-72). They generally cost less and require less power. Most important, they can be more than a thousand times faster than relays.

Solid-state logic circuit input signals are used to slightly vary voltage rather than operate contacts. These signals can be designed as low and high. A low voltage (0 V) might be used to open the circuit, while a higher voltage (+5 V) could

Figure 36-71 Solid-state relays.

(a)

(b)

be used to close it. Since this voltage is low, it consumes little power, but an output amplifier is still required for the actuating device, such as a solenoid. The output amplifier will increase the low-voltage/low-current power to higher-voltage/higher-current output power.

Relay Logic Compared to Solid-State Logic

It is obvious from the descriptions of both systems that electronic solid-state logic systems are faster, cheaper, lighter, and last longer than conventional relay-logic systems. The older conventional relay systems will continue to be replaced. However, relay systems still do have a few distinct advantages. If the circuit is small and simple, they can actually be a cheaper alternative. Outside extraneous noise pickup and signals will not affect relay operation but can raise havoc on some solid-state systems. Solid-state components will generate a lot of heat and need to be cooled, while relays are capable of operating in higher-temperature locations. One last most important consideration is the technician. Many technicians in the field have been trained on relay logic and they fully understand it, which is not the case with many solid-state electronic circuits.

36.20 TRANSDUCERS

Transducers are electrical or electromechanical devices that are often used to provide a control signal (Figure 36-73). They can be used to sense changes in pressure, temperature, light, sound, and vibration. They are most often semiconductors that convert mechanical force into an electrical signal. The signal is used by a control device or microprocessor to stop, start, or adjust a system's operation. For example, a vibration sensor located on a large air handler would stop the motor when excessive vibration occurred. Another example would be a water depth gauge, which would sense water pressure in a container. This signal could be used to stop or start a pump or turn a water valve on or off.

Because transducers are relatively low in cost and have high reliability, they are used frequently to provide remote sensing for HVACR equipment. Transducers have increased the life of systems and improved operating efficiencies by providing constant monitoring.

Figure 36-73 Pressure transducer and electrical lead.

36.21 SOLID-STATE COMPONENTS

Circuits using solid-state components are different than conventional mechanical switching devices because the electrons are confined entirely within the solid material. Some common solid-state components include transistors, diodes, and silicon rectifiers.

Semiconductors

Some materials are good conductors of electricity, while others are insulators. A semiconductor is a material that is neither a good conductor nor a good insulator. Semiconductor materials are often made from germanium and silicon. These materials, due to their peculiar crystalline structure, may under certain conditions act as conductors and under other conditions act as insulators. This ability to either conduct current or block current flow can be useful in a control circuit.

Transistors

Transistors were one of the first most popular solid-state devices used and became well known for the mass production of transistor radios. They can be used as a switch or to amplify an electrical signal. As an example, in a HVACR system, these can be used to amplify a signal of low-voltage/low-current power to a higher-voltage/higher-current power to operate a relay.

Diodes

A diode is a semiconductor that acts similar to a check valve, allowing for one-way flow through an electrical circuit. A diode has an anode and a cathode (Figure 36-74). If the anode is connected to the positive terminal, then the diode is forward biased and current will flow. If the anode is connected to the negative terminal, then the diode is reverse biased and no current will flow. Diodes can vary from the size of a pinhead to much larger sizes for ratings of 500 amperes or more (Figure 36-75).

Silicon Rectifier

Using the principle of the diode, a simple full wave-bridge rectifier can be configured to convert alternating current into direct current. Rectifiers are commonly used because many devices such as meters and control systems often require DC power. Power supplies for battery-operated devices such as cell phones and laptop computers require AC to DC converters. Figure 36-76a shows the current flow to a direct current meter through diode rectifiers 3 and then 2. When the AC current reverses, the meter will still

Figure 36-74 Diode showing anode and cathode.

Figure 36-75 Common diodes.

be operating on direct current with current flow through diode rectifiers 1 and 4, as shown in Figure 36-76b. Silicon rectifiers can be designed to operate throughout a wide range of current and voltage levels and are therefore used on many different types of applications (Figure 36-77). They are small, lightweight, and can be made shock resistant. Silicon rectifiers can have efficiencies as high as 99 percent.

Figure 36-77 Silicon rectifier.

Silicon-Controlled Rectifier (SCR)

The increased concern about energy efficiency has led to more systems using variable and controlled power. There are a number of examples, such as lighting, that can be adjusted through a range rather than always at a maximum brightness. Refrigeration compressors and fans use variable-speed motors that can slow down or speed up depending on the demand.

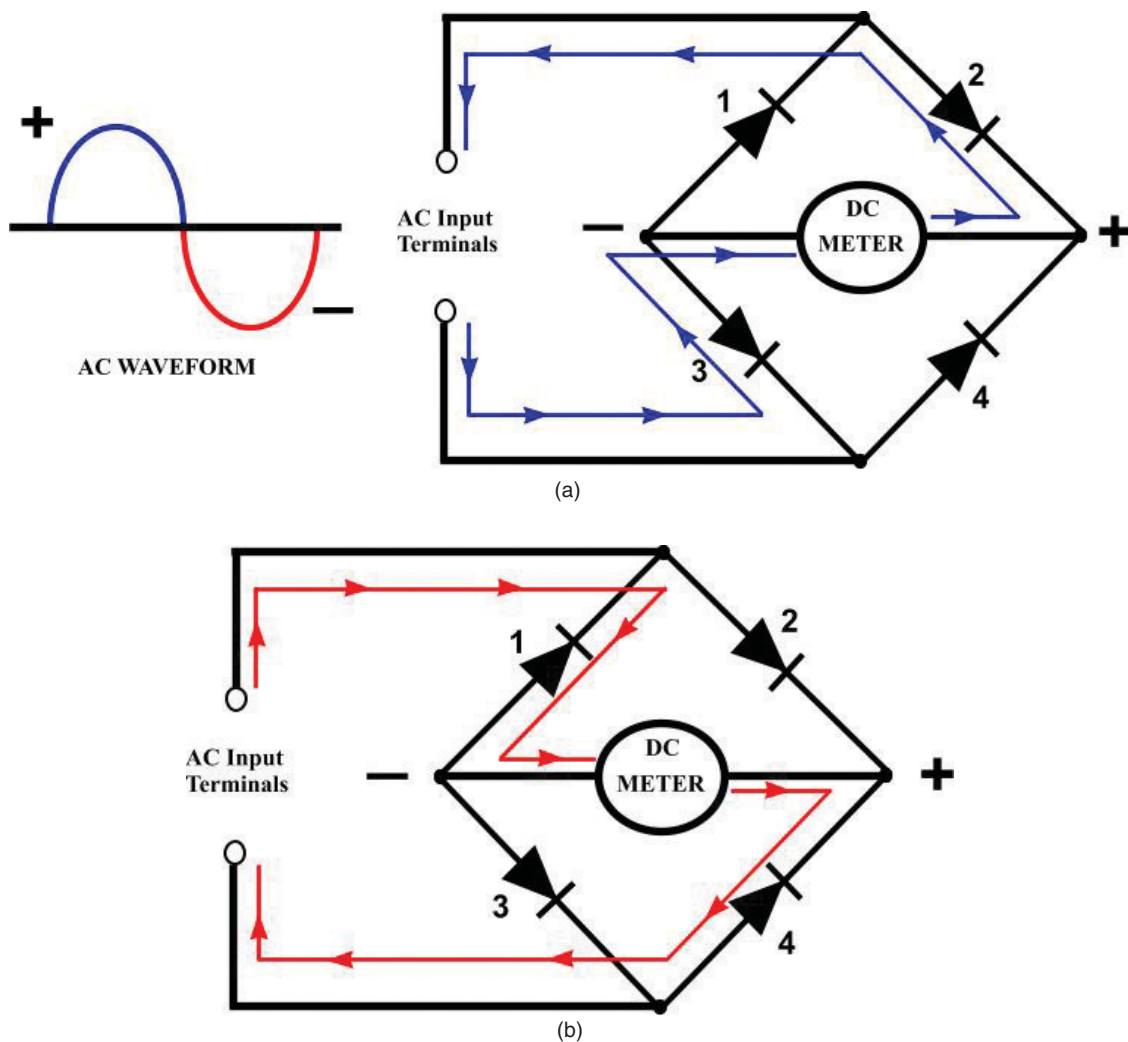

Figure 36-76 (a) Full-wave silicon rectifier; (b) full-wave silicon rectifier with opposite current flow.

Figure 36-78 Silicon-controlled rectifier with gate control.

Figure 36-79 TRIAC bidirectional device.

Conventional systems use large, expensive transformers that allow for a variable adjustable secondary coil output. These are being replaced by silicon-controlled rectifiers (SCRs) because they are small, relatively inexpensive, require virtually no maintenance, and are very efficient. They can be found in small control circuits as well as in large circuits of several hundred amperes with operating voltages over 1,000 V.

The SCR is similar to a diode in that it will block reverse current. The difference is that the SCR can also block forward current. More important, it can be switched electrically to allow forward current conduction by a pulse of current flowing through its gate (Figure 36-78). When the SCR is triggered by a gate pulse, conduction begins. The important application for an SCR is that it can be turned on and off like a switch without the need for electrical contacts. The speed of switching is also much faster than traditional contacts, and the timing can be varied during operation. A TRIAC, shown in Figure 36-79), is a bidirectional device of two SCRs connected in parallel-opposed with a common gate. A positive voltage applied to the gate will “fire” the TRIAC in either direction.

UNIT 36—SUMMARY

Resistors and capacitors are commonly found in most circuits. Electronic circuits often use variable resistors that allow for adjustment. Capacitors are used for many applications, such as tuning, filtering, energy storage, power factor correction, and motor starting. Transformers have primary and secondary windings that can be configured to step up or step down the voltage. A motor powered by a 440 line voltage will normally require a step-down transformer to lower the voltage for the relays and controls. Fuses and circuit breakers are used to limit the current flow in a circuit to avoid overheating and fire. Switches, relays, and contactors are used to close and open circuits. Relays can be used in combination to start, stop, and engage safety cutouts. This type of relay logic is quickly being replaced by solid-state logic, but many systems still combine some combination of both.

Electric Motors

OBJECTIVES

After completing this unit, you will be able to:

1. describe the operation of AC induction motors.
2. explain the importance of torque, speed, and power usage for motors.
3. explain how and why capacitors are often used for single-phase motors.
4. list the different types of single-phase motors.
5. describe the differences between single-phase and three-phase motors.
6. list the different types of motor-protection devices.
7. test a motor circuit for proper operation.

37.1 INTRODUCTION

Electric motors are the most important load device in the various types of HVACR units. They convert large portions of electrical energy to useful work. It is important, therefore, for the technician to understand how they operate and how they can be protected. It is also important to note that not all motors are exactly the same because different motors are designed for various types of service. Even though all motors are not the same, they all share the important characteristics of torque, speed, and power usage.

37.2 AC INDUCTION MOTOR TORQUE

Torque is the twisting (or turning) force that must be developed by a motor to turn whatever it is driving. The power required for a motor to drive a fan, compressor, or any other piece of equipment is directly related to the torque and speed required. A greater amount of torque is required to start a motor than to run it. The starting torque requirements for a fan are low. The starting torque requirements for a reciprocating compressor are high. Providing extra starting torque is expensive. Therefore, to keep the cost down the motor is selected with the smallest torque that will adequately perform the work for which it is intended.

TECH TIP

Manufacturers can produce motors with high starting torque, high running torque, or good running efficiency. It is impossible, however, to produce a single motor that has all three characteristics. The performance required of motors will determine what type of motor to use. Motors that frequently start but do not run for long periods of time would benefit from high starting torque. Motors that operate for long periods of time under heavy loads would benefit from having high running torque. Motors that operate for long periods of time under relatively light loads will benefit from good running efficiency. Manufacturers of equipment take these three factors into consideration when specifying which motor is to be used. For that reason, it is recommended that you select a replacement motor within the same category as the one originally supplied with the equipment.

37.3 INDUCTION MOTOR PRINCIPLES

The two principal parts of a motor are the stator and the rotor. The stator is the stationary part, and the rotor (often referred to as the armature) is the rotating part, as shown in Figure 37-1. The stator core is built of slotted

Figure 37-1 Parts of an electric motor: (a) rotor; (b) stator.

Figure 37-2 Squirrel cage-type rotor.

steel laminations. Coils of wire called windings are spaced in the **stator** slots. When current is applied to a stator coil, a magnetic field is generated. Depending on the direction of current flow through the coil, either a north or a south pole will be produced. Each winding can be considered a pole.

The **rotor** is a series of aluminum (or copper) bars mounted on a soft iron core. The core provides a path for the magnetic field of the rotor. The conductor bars are shorted together by an end ring permitting current to flow, as shown in Figure 37-2.

The current passing through the stator creates a powerful magnetic field, as shown in Figure 37-3. No current is actually supplied to the rotor. Instead, the magnetic field of the stator induces current to flow through the rotor. This current **induced** in the rotor will also produce a magnetic field. However, the current induced in the rotor is in the opposite direction from the stator current. This flow of current in the opposite direction creates an opposing magnetic field in the rotor, which reacts with the stator field. The repulsion and attraction between the poles of the rotor and the stator cause the rotor to turn.

Figure 37-3 The induced magnetic field in the conductor bars is the same as the electromagnetic field; because just as magnetic poles repel each other, the rotor is forced to spin as the fields repel each other.

Figure 37-4 The magnetic field induced in the rotor causes it to rotate.

As shown in Figure 37-4, the like poles (north to north and south to south) in the stator coil repel the like poles in the rotor winding, causing rotation. In Figure 37-5, the rotor winding is shown with both north and south poles relatively near each other. The stator coil repels the like poles and attracts the opposite poles.

As the alternating current in the stator coils changes direction, their polarity also changes. The north pole coils now become south poles and vice versa (Figure 37-6). The current flow through the rotor also reverses direction, so the polarity of the rotor changes along with the polarity of the stator. Even though the current is alternating, a continuous rotation is produced.

A problem can occur if the rotor is stopped in the position shown in Figure 37-7. In this position, regardless of polarity, no motion can occur. This position is sometimes described as dead center. To correct this condition, a start winding is added, as shown in Figure 37-8. The original winding is called a run winding. The two windings—the run winding and the start winding—are out of phase with each other, and enough torque is created to start the rotor turning. Motors of this type are called **split-phase motors**.

Figure 37-5 On one side the like magnetic poles are being repelled, and on the other side the opposite poles are being attracted.

(a)

(b)

Figure 37-6 (a) In the first half of the AC power cycle, the rotor is pushed away from one side and attracted to the other; (b) in the second half of the AC power cycle, the current direction through the windings changes and the process is repeated; this is what keeps the motor spinning.

Figure 37-7 A motor cannot start rotating if the magnetic fields are at dead center.

Figure 37-8 Start windings are offset from run windings to get the rotor out of dead center; start windings are often made of finer wire than run windings.

Because of their low starting torque, they are used only on fractional horsepower applications.

37.4 MOTOR SPEED

The speed of a motor is determined by the number of poles (stator coils) and the frequency (hertz) of the alternating current. A greater number of poles results in slower motor speeds. Higher frequency produces faster motor speeds. Speed is measured in revolutions per minute (rpm). The maximum speed of a motor is known as the **synchronous speed**.

CAUTION

The rpm of induction motors is totally dependent on the number of poles and the frequency of the alternating current. An induction motor will turn at the same rpm even though the voltage supplied to the motor is lowered. However, as the voltage is decreased, the current the motor draws increases. Motors that are operating at a low voltage will quickly overheat and may fail. It is for that reason that rheostat motor controllers should not be used on induction motors.

Motors are not 100 percent efficient. In actual performance, there is some slippage, or inefficiency, in the motor operation. For motors used to power HVACR equipment, the actual speed is usually 95–97 percent of synchronous speed. Figure 37-9 shows two-pole, four-pole, six-pole, and eight-pole motors. The number of poles is used to calculate the synchronous motor speed.

The following is an example of calculating synchronous motor speed. The formula is:

$$\text{rpm} = \frac{\text{Hz} \times 60 \text{ sec/min}}{\frac{1}{2}p} \text{ or } \frac{\text{Hz} \times 120}{p}$$

where

rpm = revolutions per minute

Hz = frequency in cycles/sec

p = number of poles

EXAMPLE 37-1: SOLVING FOR THE SPEED OF A MOTOR

What is the speed of a four-pole motor operating at a frequency of 60 Hz?

$$\text{rpm} = \frac{60 \times 120}{4}$$

$$\text{rpm} = \frac{7,200}{4}$$

$$= 1,800 \text{ revolutions/min}$$

37.5 CAPACITOR PRINCIPLES

A capacitor is made up of two conductors separated by an insulating material. The conductors are called plates and the insulating material is the **dielectric**. Referring to Figure 37-10, when voltage is applied, the current through the capacitor resistor circuit will lead the voltage. To provide strong starting torque for a split-phase motor, a start capacitor is placed in series with the start winding (Figure 37-11). When voltage is applied, the magnetism in the start winding will occur earlier than in the run winding and will provide the push needed to start the motor. Figure 37-12 shows the use of the phase shift to advance the magnetic field in the start winding.

When the current direction in the start winding reverses, the polarity of the start winding will also change. By this time, the rotor south magnetic pole has rotated to the point where it is repelled by the new stator south pole, causing continuous rotation.

A capacitor is rated by its capacity and voltage limit. The unit of capacity is the microfarad (mfd and μF are commonly used abbreviations). A high mfd rating is obtained by either using large plates or a small amount of insulation. A low mfd is obtained by using smaller plates or more insulation. The voltage stamped on the outside of the capacitor is the maximum voltage that can be connected safely across the capacitor. If this voltage is exceeded, the capacitor is likely to fail.

SERVICE TIP

There is often a misunderstanding that a capacitor provides the motor with higher voltage. This is because often on the side of the capacitor there is a much higher voltage listed than the actual voltage at which the system operates. For example, 377 is a common voltage listing for capacitors. However, capacitors do not add voltage but merely shift the phase to increase the running efficiency or starting torque. Capacitors in motor circuits are subjected to higher voltages than the voltage powering the unit. The high voltage across the capacitor is the result of the charging and discharging of the capacitor in series with an inductive load.

Figure 37-9 Synchronous speed depends on the number of poles.

Figure 37-10 (a) The voltage and current flow through a resistor, like the lightbulb load in this circuit, at the same time; (b) however, in the capacitor resistor circuit, the current leads the voltage through the circuit.

Figure 37-11 The phase shift caused by the capacitor causes the rotor to move, even if it is dead center.

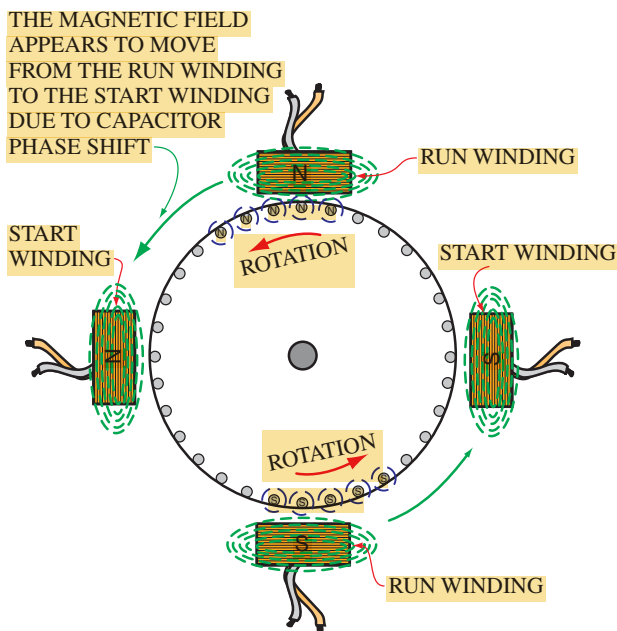

Figure 37-12 Rotating magnetic field due to capacitor phase shift.

Figure 37-13 Run capacitor connected to the power and start terminals of the fan motor.

Capacitors are used to achieve the desired phase angle shift and to obtain the required current through the series load. Both of these qualities are obtained by selecting the proper mfd rating.

Additionally, whenever a start capacitor and its relay are connected to a compressor motor, the start capacitor and the relay normally closed (NC) switch are in series with the start winding. The start relay coil is connected in parallel with the start winding. With this arrangement, the starting torque of the motor is increased. The relay removes the start capacitor from the circuit as soon as the motor is running.

Referring to Figure 37-13, a run capacitor has been connected to the power and start terminals of the fan motor. The run capacitor stays in the circuit all the time and increases the efficiency of the motor. If the run capacitor should fail, the current draw of the motor would be increased and the motor could overheat. Most PSC motors will not operate if the run capacitor is defective.

Figure 37-14a shows the normal appearance of the run capacitor. The run capacitor, which stays in the circuit continuously, is made of large plates and a large amount of insulation (dielectric) to dissipate the heat. The run capacitor may also be round. The start capacitor does not stay in the circuit long and therefore does not have a heat-dissipation problem. It is typically made in rolled form, sandwiching metal foil and insulating material (Figure 37-14b).

37.6 SINGLE-PHASE MOTORS

There are a number of different types of single-phase motors. They differ from each other mainly by the amount of starting and running torque. The following types are the most commonly encountered:

- Permanent split capacitor (PSC)
- Capacitor start (CS)
- Capacitor start/capacitor run (CSCR)
- Shaded pole
- Split phase

Permanent Split Capacitor (PSC) Motor

The permanent split capacitor (PSC) motor has a run capacitor in series with the start winding, as shown in Figure 37-15. This capacitor stays connected at all times. It starts

(a)

(b)

Figure 37-14 A comparison of the physical shape of start and run capacitors: (a) run capacitor; (b) start capacitor.

Figure 37-15 Permanent split capacitor (PSC) power.

the motor and then is left in the circuit to improve the efficiency of the motor after it is running.

The run winding has the number of turns of wire required to give the best motor performance at a given line voltage. The start winding has more turns of smaller wire, which gives it a higher resistance and lower current-carrying capacity than the run winding.

The PSC motor will always have the common connection for the two windings attached to power. The run capacitor will be connected between the start winding and the run winding. The run capacitor therefore improves the performance of the motor both in starting and running.

SERVICE TIP

It is important that the proper size run capacitor be used with a PSC motor. If the capacitance changes more than 10 percent from the design capacitance, the motor windings will build up greater heat as they operate. If enough heat builds up, the motor can become damaged. It is therefore very important that the exact capacitor as specified by the manufacturer be installed on any PSC motor.

The PSC motor has moderate starting torque and good running efficiency. It is used to power fans and small compressors. The low mfd rating of the run capacitor results in a small phase angle shift, creating only a moderate starting torque.

Capacitor Start Induction Run (CSIR) Motor

A diagram of the capacitor start induction run (CSIR) motor is shown in Figure 37-16. This motor has a high starting torque but is not as efficient as the PSC motor. The reason for its lower efficiency is that the capacitor is switched out of the circuit immediately after starting. This motor has a high-mfd start capacitor.

There are two ways that the start capacitor can be removed from the circuit:

- **Mechanical switch** This is a **centrifugal switch** attached to the motor shaft. When the motor reaches $\frac{2}{3}$ or $\frac{3}{4}$ of its rated speed, centrifugal force opens the switch (Figure 37-16).

Figure 37-16 Capacitor start induction run (CSIR) motor.

- Electromagnetic method** A potential relay is placed across the start winding. Its contacts are placed in series with the high-mfd capacitor. When the motor is started, the capacitor produces a high starting torque. As the motor speed increases, the induced voltage across the start relay coil increases until it reaches a preset value higher than the line voltage. The relay coil is energized and the NC switch is opened, removing the start capacitor from the circuit.

Capacitor Start Capacitor Run (CSCR) Motor

The capacitor start capacitor run (CSCR) motor has both a start capacitor and a run capacitor (Figures 37-17 and 37-18). It has excellent starting and running torque but is not as efficient as the PSC motor. It is used to drive most compressors.

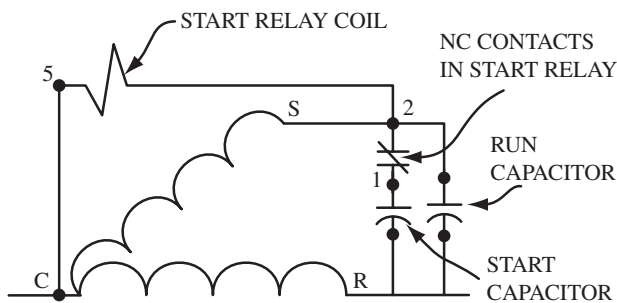

Figure 37-17 Capacitor start capacitor run (CSCR) motor.

Figure 37-18 CSCR motor diagrams.

Start Kits

Start kits are available for the technician's use whenever it is necessary to improve the starting torque of a motor. When a motor keeps tripping out on overload, the addition of a start kit may solve the problem.

Where a high starting torque is required, a hard-start kit can be installed. Where low voltage or a voltage lag is experienced, a soft-starting kit can be used. A hard-start kit contains a start capacitor and a start relay; a soft start assist uses a PTC device.

SERVICE TIP

Often start capacitors have bleed resistors connected between the two capacitor terminals. The purpose of this bleed resistor is to drain the capacitor's voltage during the motor's off cycle. This is done so that when the motor contactor starts the motor, there is not a capacitor discharge across the contactor's points. Such a discharge causes pitting of the contactor. Over time, this pitting will destroy the contacts. Bleed resistors are available from the supply house to be installed on start capacitors. If one is not installed, the contactor in the unit will become pitted and in some instances weld or stick together.

Positive Temperature Coefficient (PTC) Thermistor

A different soft-starting kit is available to be applied to PSC motors. This kit includes a positive temperature coefficient (PTC) thermistor. The PTC is a temperature-sensitive device whose electrical resistance will increase as its temperature increases. This PTC is placed across the run and start terminals, parallel to the run capacitor of a PSC motor, as shown in Figure 37-19.

At room temperature, the PTC thermistor has a low resistance, about 25 or 50 Ω . When voltage is supplied, an initial surge of high current passes through the start winding. This is because the thermistor is effectively shorting out the capacitor. The surge causes an increased starting torque to start the motor. The temperature increase that results causes the PTC thermistor resistance to rise, removing the short from across the run capacitor. The motor then runs as a normal PSC motor.

Figure 37-19 PTC start systems are sometimes referred to as soft start because they do not provide as much initial torque as a start capacitor and potential relay.

Shaded Pole Motor

The shaded pole motor (Figure 37-20) has a modified stator pole. A groove separates a small portion of the stator pole from the rest of the pole. A bank of metal is placed around the smaller section of the pole, which provides a phase shift needed to start the motor. Shaded pole motors have a low

starting torque, and their speed control under varying load conditions is poor. They offer a low-cost motor for light-duty applications such as running blowers on small air-handling and heating units.

Split Phase

A split-phase motor has very low starting torque and is used for applications that have easily started loads. This motor is seldom used in sizes larger than $\frac{1}{3}$ hp. The principle for operation is that two parallel connected motor windings are placed 90° apart. If the windings are identical, then the current through both will lag the voltage by the same phase angle. To generate a revolving magnetic field, one winding has a greater resistance and a lower reactance, so that the currents through the two windings are shifted in time phase. The high-resistance winding is called the starting or auxiliary winding, and the low-resistance winding is called the main winding. The starting winding is usually disconnected by a centrifugally operated switch when the motor reaches 70–80 percent of synchronous speed.

37.7 MULTIPLE-SPEED BLOWER MOTORS

Blower motors have multiple speed settings often referred to as low, medium, and high—or low, medium-low, medium, medium-high, and high depending on the number of speed taps that the motor has. These speed taps do not actually change the motor's rpm. **A motor's rpm is based on the number of poles and frequency.** By changing the speed taps on a motor, the motor's effective horsepower is changed. By changing the motor output horsepower, the motor will turn at a different rate under different load conditions. For example, a $\frac{1}{3}$ -hp motor rated at 1,750 rpm will turn at approximately 1,750 rpm when the motor is on the high setting. However, when the motor is on the medium setting, it may produce only $\frac{1}{4}$ hp. Although it is attempting to turn at the same speed of 1,750 rpm, it cannot because the load causes the motor to slow down, effectively reducing the rpm and CFM output of the blower. When the blower motor is on the low speed setting, it may produce only $\frac{1}{8}$ hp. This would result in an even lower rpm and blower CFM output.

37.8 THREE-PHASE MOTORS

Three-phase motors have the following advantages over single-phase motors:

- They are easily reversible. The direction of rotation can be changed by interchanging any two supply voltage lines (Figure 37-21).
- There is less running torque pulsation because at least one phase is always producing an induced rotational effect on the rotor.
- They have higher starting torque because each winding is out of phase with the other windings and produces rotational torque.
- They have higher efficiency.

(a)

(b)

Figure 37-21 (a) To reverse rotation, switch any two lines; (b) three-phase motor starter.

Figure 37-22 Three sets of wires, one for each phase.

CAUTION

Do not attempt to run a three-phase motor on single-phase power. When wiring the motor, you will find three separate groups of wires for the three different phases, often referred to as “legs” (Figure 37-22). Although the motor may start, it will quickly overheat and damage the windings. The same thing will happen to a three-phase motor if one of its legs of power is lost as the motor is being operated. For that reason, some large motors have single-phase or lost-leg motor protection systems, which will shut the motor down anytime a single leg of power is lost to the motor.

The windings of a three-phase motor are 120° apart, which facilitates starting. Figure 37-23 shows a schematic drawing of a three phase motor. No capacitors, no auxiliary windings, and no switching circuits are required. Three phase motors create their own starting torque.

There are three different phase windings: A, B, and C. Figure 37-24 shows a three-phase, two-pole induction motor, using a wye configuration. The phases are mechanically offset from one another by 120° , and the winding currents are 120° electrically phase shifted. Although poles are represented in the diagram for ease of illustration, actual motor windings are put into slots in the rotor as winding groups. Distributive windings will have a number of windings in a series-connected group. The motor shown in Figure 37-25 has thirty-six slots around its circumference. Two slots are required for each winding, so it provides slots for eighteen windings or six windings connected in series per phase.

Three-phase motors are wired in either a delta configuration (Figure 37-26) or a wye configuration (Figure 37-27). The delta configuration is named because the circuit resembles the triangle shape of the Greek letter delta (Δ). The wye

configuration resembles a capital letter Y. In the delta configuration, the line voltages equal the phase voltages, and the line currents are 1.732 times the phase currents. In the wye configuration, the line voltages equal 1.732 times the phase voltages, and the line currents equal the phase currents.

37.9 MOTOR PROTECTION

There are a number of causes of motor failure. **The most common problem is excessive heating.** Among the causes of excessive heating are the following:

- Defective start relay (on a single phase motor)
- Excessive load
- Loss of refrigerant on a gas-cooled motor
- Excessive time on locked rotor current
- Operation at too high or too low voltage
- Single phasing (on a three-phase motor)

All motor protective devices are designed to cut off the power to the motor before damage has occurred. Repeated cycling on the protective device can damage a motor.

The locked rotor current is the momentary starting current. This current can be 3–5 times the running current of the motor. If the motor is blocked from starting, this excessive current will be prolonged, causing heating and serious

Table 37-1 Voltages Handled by Common Motors

Nameplate	Upper Limit	Lower Limit
208	228	188
230	253	207
460	506	414
575	633	518

damage. A protective device is therefore required to disconnect power on either excessive temperature or excessive current. Fuses or circuit breakers are most often the devices that protect against excessive starting current.

All motors are designed to operate between certain voltage limits. If voltages outside these limits are applied, the life of the motor can be seriously reduced. Table 37-1 shows the limits of voltage that common motors are designed to handle.

Typically motors are designed to be applied within ± 10 percent of the nameplate voltage (Figure 37-28). Dual-rated motors such as 208 V/230 V may be rated plus 10 percent, minus 5 percent. The manufacturer's information should be referenced.

On three-phase motors, if the voltage varies more than 2 percent between phases, the life of the motor will be reduced. This is caused by unequal currents and heating.

Single phasing is another serious problem common to only three-phase motors. If the motor loses power in one of the three lines, the motor may continue to operate. This is called single phasing. This will cause sufficient unbalancing to increase the motor temperature and require motor protection.

37.10 TYPES OF MOTOR PROTECTION

There are three types of protective devices that are used to protect the motor against excessive heat:

- Temperature actuated
- Current actuated
- Combination of current and temperature

These devices can be either pilot-duty overload or line-duty overload arrangements, as shown in Figure 37-29.

SAFETY TIP

Motor protection for fractional horsepower compressors is often provided by an external snap disk (Klixon) that clicks onto the compressor case. These devices are wired into the common power lead and are located inside of the terminal cover. They are supposed to be in direct contact with the compressor case to sense its temperature. If the cover is not placed back on the terminal, or if the device is not in direct contact, it will not sense the temperature of the compressor. These devices are designed to open when the temperature and/or current exceeds the compressor's limits. They will not provide the proper protection for the compressor unless they are installed correctly.

(a)

(b)

Figure 37-28 (a) Single-phase fan motor nameplate; (b) notice this motor has nameplate data for both 50 or 60 Hz.

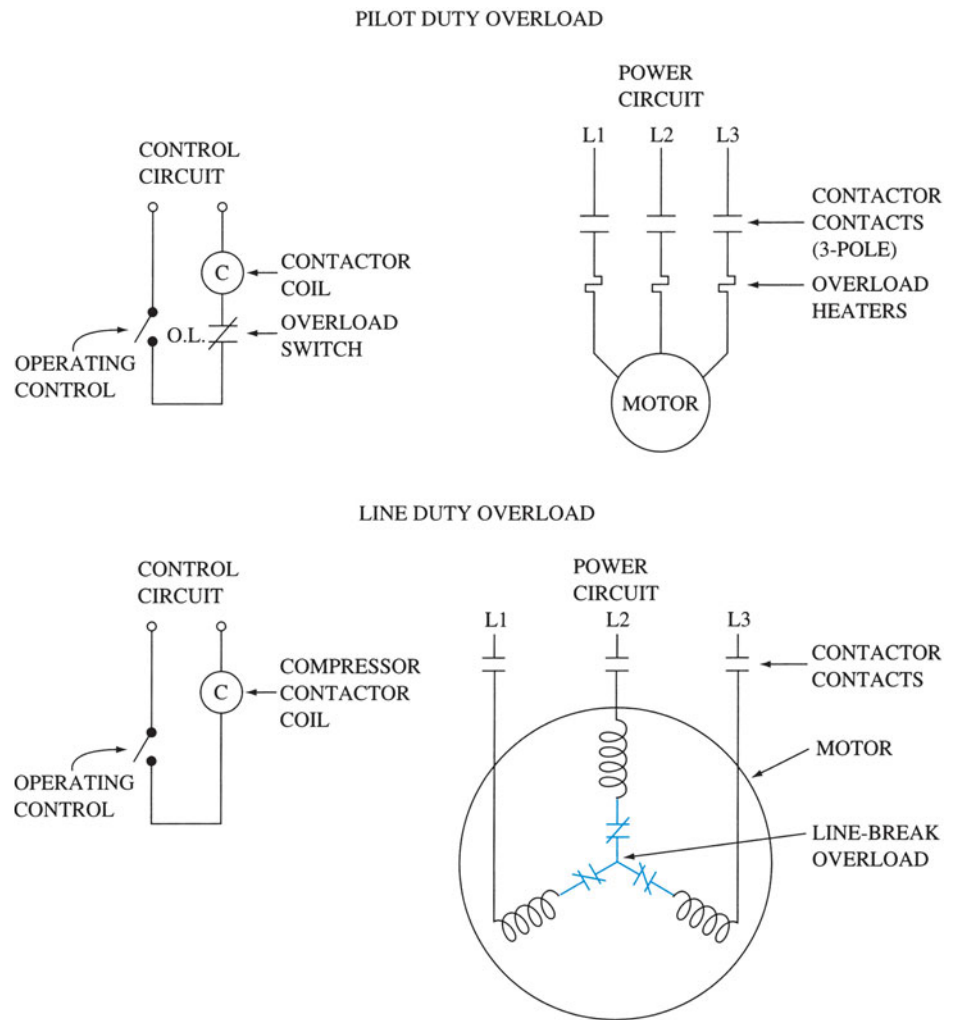

37.11 MOTOR OVERLOAD DEVICES (LINE BREAK)

For a single-phase motor, the overload device must interrupt one of the motor leads. For a three-phase motor, the device must interrupt two or three of the motor leads. On a wye-connected motor with a built-in overload device, this is often where the three windings are connected in common.

In a three-phase motor, a pilot-duty device senses current overload or excessive temperature within the motor and opens the contactor circuit to remove power to the motor. A line-duty device senses current and/or temperature in the motor winding and, if an overload occurs, will disconnect power by directly opening the motor winding circuit.

The line-duty arrangement is commonly found on compressor motors used for domestic service. Most of these reset themselves automatically. However, since they are embedded in the motor winding, as shown in Figure 37-30, it takes some time for the motor to cool down. During this waiting period it is easy to incorrectly diagnose the problem as compressor failure.

Figure 37-29 Two types of motor protection.

37.12 TYPES OF RESET

After a protective device has opened or tripped out, it needs to be reset. This can be done manually or automatically. The advantage of manual reset is that a service technician has

the opportunity to examine the cause of the problem before resetting the protective device. The advantage of the automatic reset is that the unit can automatically go back into service in the case of a nuisance trip-out.

General automatic reset devices are employed only where the time to reset is sufficient to ensure that the motor will not short-cycle and be damaged by the protective device itself. Sometimes the protective device will reset automatically, but the control circuit will require resetting by switching the unit off then on from the thermostat or control switch.

37.13 TYPES OF OVERLOAD DEVICES

The various types of overload devices that will be discussed are as follows:

- Motor starter
- External supplemental overload current or current temperature
- Internal current and temperature overload
- Thermal overload relay
- Heater element current overload

Figure 37-31 Motor starter.

- Magnetic overload (Heinemann)
- General Electric Thermotector
- Three-phase overload

Motor Starter

A motor starter is a contactor with motor overload protection added. Starters made for three-phase motors will have protection on each leg (for a total of three overloads). A motor starter is shown in Figure 37-31.
